Abstract

We study how the round-off error changes the statistical properties of a Gaussian long memory process. We show that the autocovariance and the spectral density of the discretized process (i.e. the process with round-off error) are asymptotically rescaled by a factor smaller than one, and we compute exactly this scaling factor. Consequently, we find that the discretized process is also long memory with the same Hurst exponent as the original process. We consider the properties of two estimators of the Hurst exponent, namely the log-periodogram regression and the Detrended Fluctuation Analysis (DFA). By using numerical simulations and analytical considerations we show that the estimators of the Hurst exponent of the discretized process are severely negatively biased. We compute the asymptotic properties of the DFA for a generic long memory process and we apply the result to discretized processes.

Keywords: Long-memory processes, Round-off error, Measurement error, Log-periodogram regression, Detrended fluctuation analysis

1. Introduction

"All economic data is discrete" (Engle and Russell (2004)). Round-off errors occur whenever a real valued process is observed on a grid of discrete values. A special case of round-off error is obtained by taking the sign of a real valued process. Round-off errors change the properties of the original stochastic process. Few exact results exist on the effect of round-off error on stochastic processes. Delattre and Jacod (1997), for example, proved a central limit theorem on a Brownian motion with round-off error sampled at discrete times. In this paper we study analytically and

numerically the effect of round-off error on long memory processes. We will use the term *discretized process* to refer to the process with round-off error and the term *discretization* to refer to the rounding procedure.

Round-off errors can be either due to a limit in the resolution of the observing device or to the fact that an underlying real valued process can manifest itself only as a discrete valued process. When seen as a resolution effect, round-off error can also be considered as a special case of measurement error. One recent strand of econometric literature considers the problem of estimation of a process that can be observed only with some noise due to the measurement process. The typical modeling approach is to consider the measurement error as an additive white noise process uncorrelated with the unobserved latent process (see, for example, Hansen and Lunde (2010)). Round-off error can be considered as a different form of measurement error, which is a deterministic function of the underlying latent process and it is not uncorrelated with it.

An important example of round-off error due to the fact that the process manifests itself only as a discrete valued process is the dynamics of asset prices. Despite the fact that the price of an asset is a real number, transaction prices (but also quote prices) can assume only values which are multiple of a minimum value called tick size. For transaction by transaction data the tick over price ratio can be large leading to a price dynamics that cannot be even approximated as a real valued process. In the market microstructure literature the round-off error is one of the main sources of disturbance in the estimation of integrated volatility. Several papers have considered how tick size affects the diffusion dynamics of price on short time scales. For example, Gottlieb and Kalay (1985) and Harris (1990) developed microstructure models to investigate the effect of price discretization on return variance and serial correlation. More recent papers consider the effect of price discretization on phase portrait of returns (Szpiro (1998)), on price-dividend relation (Bali and Hite (1998)), and on integrated volatility (Rosenbaum (2009)). See also La Spada *et al.* (2011) and references therein for a recent review of the effect of tick size on the diffusion properties of financial asset prices. Beside market microstructure, discretized processes emerge naturally in discrete choice models, binned data, computer vision, detectors, and digital signal processing. Recently, the effect of discretization has also been studied in the framework of rational inattention (Saint-Paul (2011)).

Long memory processes are ubiquitous in natural, social, and economic systems (see Beran (1994)). However, a large part of the theory, statistics, and modeling of long memory processes is based on the assumption of normality of the distribution and very often also on the hypothesis of linearity of the generating mechanism. A major step toward generalization has been the paper by Dittmann and Granger (2002) that investigated the properties of a process obtained from a non-linear transformation of a Gaussian long memory process. Their main result is that when the transformation can be written as a *finite* linear combination of Hermite polynomials, the transformed process has the same or a smaller Hurst exponent of the original process, depending on the Hermite rank of the transformation (see below for a more precise definition of these terms). However, their results “need not hold for transformations with infinite Hermite expansion” (see Dittmann and Granger (2002)). Another problem is that, to the best of our knowledge, little is known about the properties of common estimators of the Hurst exponent when they are applied to non-Gaussian and non-linear time series. Note that even Dittmann and Granger (2002) did not discuss the issues related to the estimation of the Hurst exponent of non-linear transformations of Gaussian time series. The present paper contributes in this direction by presenting several results for a specific, yet important, class of non-linear transformations of a Gaussian long memory process, namely the class of discretization transformations.

In this paper we present an in-depth analysis of the properties of a stochastic process obtained from the discretization of a large class of Gaussian long memory processes. We give the asymptotic behavior of the autocovariance and of the spectral density, by computing explicitly the leading term and the order of the second term in a series expansion. We find that the autocovariance and the autocorrelation are asymptotically rescaled by a factor smaller than one, and the Hurst exponent is the same for the continuous and the discretized process. The spectral density is also rescaled for small frequencies by the same scaling factor as the autocovariance. We find an explicit closed form of this scaling factor. It is worth noting that the decrease of the autocorrelation function holds for the discretization of any Gaussian weakly stationary process, either long-memory or short-memory. Our results are consistent with those in Hansen and Lunde (2010) on the estimation of the persistence and the autocorrelation function of a time series measured with error.

We then consider two classic methods to estimate the Hurst exponent, namely the log-periodogram regression introduced by Geweke and Porter-Hudak (1983) and the Detrended Fluctuation Analysis (DFA) introduced by Peng *et al.* (1994). The log-periodogram regression is a very popular semi-parametric method for the investigation of long memory properties of generic processes. It is frequently used in empirical work in economics and financial econometrics. For the log-periodogram regression we show that most of the results in the literature on the asymptotic consistency and normality of the estimator (see Hurvich and Beltrao (1993), Robinson (1995), Hurvich *et al.* (1998), Velasco (2000)) do not hold for the discretized process. We study the bias of the log-periodogram estimator due to the high-frequency component of the spectral density. We show that this bias is much more significant for the discretized process than for standard continuous processes such as the fractional Gaussian noise (fGn) and the fractional AutoRegressive Integrated Moving Average (fARIMA) process. By comparing the periodogram of the discretized process to that of the continuous process we argue that this bias is negative.

The DFA (Peng *et al.* (1994)) is another very popular semi-parametric method for the investigation of long memory properties of generic processes. It was introduced more than fifteen years ago to investigate physiological data, in particular the heartbeat signal. Since its introduction it has been applied to a large variety of systems, including physical, biological, economic, and technological data. In a recent paper Bardet and Kammoun (2008) computed explicitly the asymptotic properties of the DFA for the fGn and for a general class of Gaussian weakly stationary long memory processes. Here we generalize their results to a non-Gaussian generic long memory process and we applied them to the discretized process. As a byproduct we show that the order of the error of the root mean square fluctuation given by Theorem 4.2 of Bardet and Kammoun (2008) is not correct for a generic Gaussian process. Because of the cancellation of a term the theorem is correct for the fGn and the fARIMA process as claimed in Bardet and Kammoun (2008). By comparing the root mean square fluctuation of the discretized process to that of the continuous process we argue that the second-order term induces a negative bias in the estimation of the Hurst exponent.

The paper is organized as follows. In Section 2 we define the class of long memory processes we consider in the present paper. In Section 3 we derive some analytical results on the distribution, autocovariance, and spectral density of the discretized process. Section 4 presents analytical and numerical results on the estimation of the Hurst exponent obtained by using the periodogram and the DFA. Finally, Section 5 concludes.

2. Long memory processes

In this paper we are interested in studying the effect of round-off error on a long memory process. There are several possible definitions of a long memory process. The very general definition we are using in the present paper is the following.

Definition 1. *A discrete time weakly stationary stochastic process* $\{x(i)\}_{i\in\mathbb{N}}$ *is long memory if its autocovariance function* $\gamma(k)$ *behaves as*

$$\gamma(k) = k^{-\alpha} L(k) \qquad for \;\; k \geq 1\,, \tag{1}$$

where $\alpha \in (0,1)$ *and* $L(k)$ *is a slowly varying function at infinity*[1].

Under this definition of long-memory processes the autocovariance function does not necessarily decay as a pure power-law. Consider the case $L(k) = \log k$, or any power of the logarithm function. The autocorrelation function of a long memory process is not integrable in k between 0 and $+\infty$ and, as a consequence, the process does not have a typical time scale.

Long memory processes can be characterized by the exponent α describing the asymptotic behavior of the autocorrelation function or equivalently in terms of the Hurst exponent H that, for long memory processes, is $H = 1 - \alpha/2 \in (0.5, 1)$. Long memory processes can also be characterized in terms of the fractional differencing parameter $d = (1-\alpha)/2 \in (0, 0.5)$. In this paper we will use interchangeably α, H, and d for characterizing the long memory properties of the process.

The class of long memory processes defined above is quite large due to the arbitrariness in the choice of the slowly varying function $L(k)$. Some of the results we will present below hold for a more restricted class of long-memory processes characterized by the properties of the slowly varying function in Definition 1.

Following Embrechts *et al.* (1997) we denote with $\mathcal{R}_0$ the set of slowly varying functions at infinity. We introduce the following definition

Definition 2. *We define the set of well behaved slowly varying function as*

$$\mathcal{L}(I, b_i, \beta_i) \equiv \left\{ l \in \mathcal{R}_0 : l(k) = \sum_{i=0}^{I} b_i k^{-\beta_i} \text{ for large } k \right\} \tag{2}$$

with $I \leq \infty$*,* $b_0 > 0$*,* $\beta_0 = 0$*, and* $\beta_i < \beta_{i+1}$ $\forall\, i = 0, 1, \ldots, I$*. Moreover the parameters* b_i *and* β_i *are such that* $\sum_{i=0}^{I} b_i k^{-\beta_i}$ *converges absolutely for large* k*.*

---

[1] $L(x)$ is a slowly varying function if $\lim_{x\to\infty} L(tx)/L(x) = 1$, $\forall t > 0$ (see Embrechts *et al.* (1997)). In the definitions above, and for the purposes of this paper, we are considering only positively correlated long-memory processes. Negatively correlated long-memory processes also exist, but the long-memory processes we will consider in the rest of the paper are all positively correlated.

Note that all the slowly varying functions which are analytic at infinity are well behaved with $I = \infty$.

We are interested here in the discretization of long memory processes characterized by a Gaussian distribution. The Gaussian time series is completely characterized by the mean (hereafter assumed to be zero), the diffusion coefficient D and the autocorrelation function $\rho(k) = \gamma(k)/D$. Two classes of Gaussian long memory processes are often considered in the literature. The first one is the fractional Gaussian noise (fGn) (see Mandelbrot and van Ness (1968)) characterized by the autocorrelation function

$$\rho(k) = \frac{1}{2}[(k+1)^{2H} + (k-1)^{2H} - 2k^{2H}] \tag{3}$$

For large k the asymptotic expansion of this expression is $\rho(k) \sim \frac{H(2H-1)}{k^{2-2H}}\left(1 + \frac{(2H-2)(2H-3)}{12}\frac{1}{k^2} + \ \ldots\right)$.

The second important example is the fARIMA$(0, d, 0)$ process whose autocorrelation[2] is

$$\rho(k) = \frac{\Gamma(3/2 - H)\Gamma(H + k - 1/2)}{\Gamma(H - 1/2)\Gamma(k + 3/2 - H)} \tag{4}$$

where $\Gamma(\cdot)$ is the gamma function. For large k the asymptotic expansion of this expression is $\rho(k) \sim \frac{\Gamma(3/2-H)}{\Gamma(H-1/2)}\frac{1}{k^{2-2H}}\left(1 - \frac{(4H^3-12H^2+11H-3)}{12}\frac{1}{k^2} + \ldots\right)$.

Note that both for the fGn and for the fARIMA processes the slowly varying function $L(k)$ is analytic at infinity and therefore it is well behaved according to Definition 2. In the following we will present results for the discretization of generic Gaussian long memory processes, and we will consider the fGn or the fARIMA as special cases.

3. The discretized process

Given a discrete-time and real valued process $\{x(i)\}_{i \in \mathbb{N}}$, the discretization procedure consists in setting a grid of points $j\delta$ with $j \in \mathbb{Z}$ and the value of the discretized variable at time i is $x_d(i) = [x(i)/\delta]\delta$, where $[z]$ is the integer part of z. The parameter δ sets the level of round-off error. This type of discretization appears, for example, whenever a weakly stationary process is discretized through a binning procedure.

The probability mass function of the discretized process is

$$p_d(x) = \sum_{n=-\infty}^{\infty} q_n \delta(x - n\delta) \tag{5}$$

where

$$q_n = \int_{\delta(n-1/2)}^{\delta(n+1/2)} p(x)dx \tag{6}$$

and $\delta(x)$ is the Dirac delta function.

---

[2] In the following we consider only fARIMA$(0, d, 0)$. Therefore, when in the following we refer to fARIMA, we mean fARIMA$(0, d, 0)$. For results on more general fARIMA see Section 4.3.

It is useful to introduce the adimensional scaling variable

$$\zeta = \frac{D}{\delta^2} \tag{7}$$

Since x is Gaussian distributed, the variance D_d of the discretized process can be calculated explicitly. For detailed analytical results on the distributional properties of the discretized process see Appendix A. Left panel of Figure 1 shows the ratio D_d/D as a function of the scaling parameter ζ. It is worth noting that this ratio is not monotonic. For small ζ the ratio goes to zero because δ is very large and essentially all the probability mass falls in the bin centered at zero. Finally, the parameter ζ sets the fraction q_0 of points which in the discretized process have value zero. It is direct to show that $q_0 = erf\left[1/2\sqrt{2\zeta}\right]$, where $erf[\cdot]$ is the error function. This is clearly a monotonically decreasing function. In the numerical examples below we will use $\zeta = 0.1, 0.25$, and 0.5 corresponding to $q_0 = 0.886, 0.683$, and 0.521, respectively.

A different type of discretization that we will consider below is obtained by taking the sign of the variable x. Assuming that the distribution function of x is absolutely continuous with respect to the Lebesgue measure in a neighborhood of 0, so that the event $x(i) = 0$ has zero probability, this discretization leads to $x_d(i) = sign(x(i)) = \pm 1$ with probability 1. Trivially, when the discretization is obtained by taking the sign function the variance of the discretized process is $D_s = 1$.

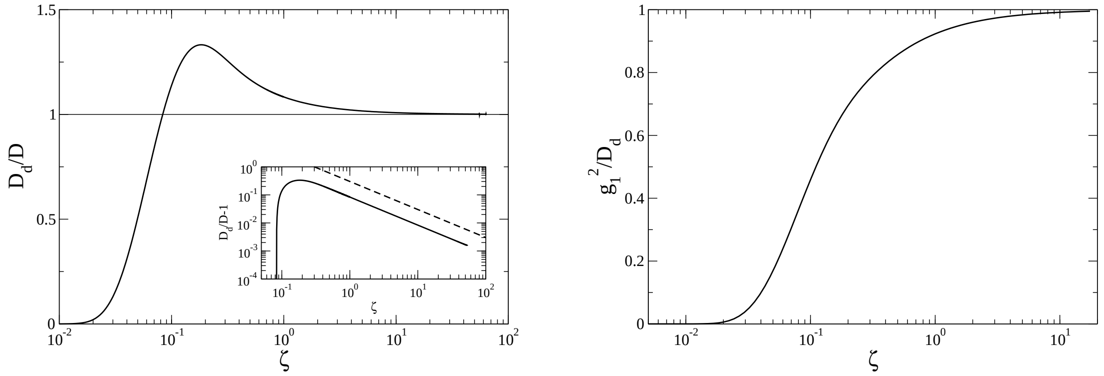

Figure 1: Left panel. Ratio between the variance D_d of the discretized process and the variance D of the original Gaussian process as a function of the scaling parameter ζ. The inset shows the fractional change $D_d/D-1$ as a function of ζ in a log log scale. The dashed line shows the ζ^{-1} behavior. Right panel. Ratio between the squared coefficient g_1^2 (see formula (12)) and the variance of the discretized process as a function of the scaling parameter ζ. This ratio is equal to the ratio between the autocorrelation function $\rho_d(k)$ of the discretized process and the autocorrelation function $\rho(k)$ for large values of lags k (see Corollary 1).

3.1. Autocovariance and autocorrelation function

In order to calculate how the time correlation properties change when a weakly stationary Gaussian process is discretized we will make use of a general theory presented, for example, in

Beran (1994) and Dittmann and Granger (2002). For the benefit of the reader we recapitulate here this approach.

We consider first the case of an underlying weakly stationary Gaussian process of unit variance. In order to extend the theory to non-unit variance we need simply to do the transformation $x \to x/\sqrt{D}$. The starting point is a series expansion of the bivariate Gaussian density function in Hermite polynomials. Hermite polynomials are an orthonormal polynomial system with Gaussian weight. Specifically,

$$\int_{-\infty}^{\infty} H_n(x) H_m(x) \frac{e^{-x^2/2}}{\sqrt{2\pi}} dx = \delta_{nm} \tag{8}$$

where δ_{nm} is the Kronecker delta. The expansion of the bivariate Gaussian density function $P(x, y)$ in Hermite polynomials is (see Barrett and Lampard (1955))

$$P(x, y) = P(x)P(y) \left[1 + \sum_{j=1}^{\infty} \rho^j H_j(x) H_j(y) \right] \tag{9}$$

where $P(x)$ is the univariate Gaussian density function and ρ is the correlation coefficient between variables x and y.

Following Lemma 1 of Dittmann and Granger (2002), if we transform two Gaussian random variables x and y with a nonlinear transformation $g(x)$ that can be decomposed in Hermite polynomials

$$g(x) = g_0 + \sum_{j=1}^{\infty} g_j H_j(x) \tag{10}$$

the linear covariance and the linear correlation of the transformed variables are

$$Cov[g(x)g(y)] = \sum_{j=1}^{\infty} g_j^2 \rho^j \qquad Cor[g(x)g(y)] = \frac{\sum_{j=1}^{\infty} g_j^2 \rho^j}{\sum_{j=1}^{\infty} g_j^2} \tag{11}$$

The proof is straightforward. The coefficients g_j in (10) are

$$g_j = \int_{-\infty}^{\infty} g(x) H_j(x) \frac{e^{-x^2/2}}{\sqrt{2\pi}} dx \tag{12}$$

The smallest $j > 0$ such that g_j is non-vanishing is called the Hermite rank of the function $g(x)$. Note that the second equation in (11) implies that any non-linear transformation of a bivariate Gaussian distribution decreases the correlation between the variables (the covariance can of course increase or decrease). When x and y describes the same process at two different times the above equations can be used to compute the autocovariance and autocorrelation properties of the transformed process.

Dittmann and Granger (2002) used the above expansion to study how the long memory properties change as a result of a nonlinear transformation that can be written as a finite Hermite expansion. (See Proposition 1 of Dittmann and Granger (2002).) They mention that this approach cannot be used if the the transformation has an infinite Hermite expansion. As we will show below, discretization can be expressed as an infinite sum of Hermite polynomials and therefore we cannot use directly Proposition 1 of Dittmann and Granger (2002). Therefore in the following we compute explicitly the asymptotic behavior of the autocovariance function and the small frequency series expansion of the spectral density and we directly obtain the long memory properties of the discretized process.

3.1.1. Discretized process

By using the theory outlined above we compute the asymptotic behavior of the autocovariance $\gamma_d(k)$ and the autocorrelation $\rho_d(k)$ of the discretized process.

Proposition 1. *Let $\{x(i)\}_{i\in\mathbb{N}}$ be a discrete time Gaussian weakly stationary process with autocovariance function given by Definition 1. Then the autocovariance function of the discretized process $\{x_d(i)\}_{i\in\mathbb{N}}$ satisfies*

$$\gamma_d(k) = \left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 k^{-\alpha} L(k) \left(1 + O\left(k^{-2\alpha} L^2(k)\right)\right) \quad \text{as } k \to \infty\,, \tag{13}$$

where $\vartheta_a(u, q)$ is the elliptic theta function.

The proof of this and of the other propositions in this section are in Appendix B. According to Definition 1, this proposition proves that the discretized process is a long memory process with the same Hurst exponent as the original process. Note that asymptotically the autocovariance of the discretized process is proportional to the autocovariance of the original process.

Moreover, as for the original process, the autocovariance function does not necessarily decay as a pure power-law. Note also that the second order corrections are nested inside the slowly varying function, and it may happen that the first order term in $O(k^{-2\alpha}L^2(k))$ dominates the second order term in $k^{-\alpha}L(k)$. This might be the case, for example, if $L(k)$ converges to a constant. To compute explicitly the second-order corrections we need to specify a functional form for the slowly varying function $L(k)$. To this end we consider long memory processes whose slowly varying function in the autocovariance is well behaved according to Definition 2. We prove the following:

Proposition 2. *Let $\{x(i)\}_{i\in\mathbb{N}}$ be a discrete time Gaussian weakly stationary process with autocovariance function given by Definition 1 and $L \in \mathcal{L}(I, b_i, \beta_i)$. Then the autocovariance function of the discretized process $\{x_d(i)\}_{i\in\mathbb{N}}$ satisfies*

$$\gamma_d(k) = \left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 b_0\, k^{-\alpha} \left(1 + O\left(k^{-\min(2\alpha, \beta_1)}\right)\right) \quad \text{as } k \to \infty, \tag{14}$$

where $\vartheta_a(u, q)$ is the elliptic theta function.

The behavior of the autocorrelation function is trivially obtained from the two above propositions. For example, for the more general case we have the following.

Corollary 1. *Under the conditions in Proposition 1, the autocorrelation function $\rho_d(k)$ of the discretized process satisfies as $k \to \infty$*

$$\rho_d(k) = \left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 \frac{k^{-\alpha}L(k)}{D_d} \left(1 + O\left(k^{-2\alpha}L(k)^2\right)\right) = \frac{g_1^2}{D_d} \frac{L(k)}{k^{2-2H}} \left(1 + O\left(k^{4H-4}L(k)^2\right)\right) \tag{15}$$

For large k, g_1^2/D_d is the ratio of the autocorrelation function of the discretized process and the underlying process. The right panel of Figure 1 shows g_1^2/D_d as a function of ζ. We observe that the more severe is the discretization, the larger is the reduction of the autocorrelation function.

We numerically tested our propositions and the error made by considering only the leading term in the asymptotic expansion. We simulated a fGn with unit variance for which $\lim_{k\to\infty} L(k) = H(2H-1)$. Figure 2 shows the sample autocovariance of the discretized process and that of the continuous process for $\zeta = 0.1$ and $H = 0.7$ and $H = 0.85$ and different sample size, namely $N = 2^{10} = 1,024$ and $N = 2^{14} = 16,384$. Before discussing this figure, we remind that the sample autocovariance (and the autocorrelation) is a biased estimator for long memory time series. Hosking (1996) showed that for a generic long memory process with an autocovariance asymptotically decaying as $\gamma(k) \sim \lambda k^{-\alpha}$ with $0 < \alpha < 1$ the sample covariance $\hat{\gamma}(k)$ has an asymptotic bias

$$E[\hat{\gamma}(k)] - \gamma(k) \sim \frac{-2\lambda N^{-\alpha}}{(1-\alpha)(2-\alpha)} \quad as\ \ N \to \infty \tag{16}$$

where N is the length of the sample time series. Since Hosking's theorem only requires that the process is long memory, we can apply it also to the discretized time series. Figure 2 shows a very good agreement between simulations and analytical results (with bias correction) of the asymptotic autocorrelation function.

3.1.2. *Sign process*

Similarly to above, we can compute the autocovariance and the autocorrelation function of the sign of a Gaussian weakly stationary process.

Proposition 3. *The autocovariance function $\gamma_s(k)$ and the autocorrelation function $\rho_s(k)$ of the sign of a discrete time Gaussian weakly stationary process with autocorrelation $\rho(k)$ is*

$$\gamma_s(k) = \rho_s(k) = \frac{2}{\pi} \arcsin \rho(k) \tag{17}$$

Therefore also the sign transformation preserves the long memory property and the Hurst exponent.

If the autocorrelation ρ is small (for example if the lag k is large) we have

$$\gamma_s(k) = \rho_s(k) = \frac{2}{\pi}\left(\rho(k) + \frac{\rho^3(k)}{6}\right) + O(\rho^5(k)) \tag{18}$$

This expression has been obtained several times, as, for example, in the context of binary time series (see Keenan (1982)).

Figure 3 shows the autocorrelation of the sign process of a fGn for different values of H together with the first approximation and the exact result. Also in this case the agreement between simulations and theory is very good.

3.2. *Spectral density*

From the Wiener-Khinchin theorem we know that the spectral density of a weakly stationary random process is the Fourier transform of the autocovariance function. We use this fact to calculate the small frequency behavior of the spectral density of the discretization of a Gaussian long memory process.

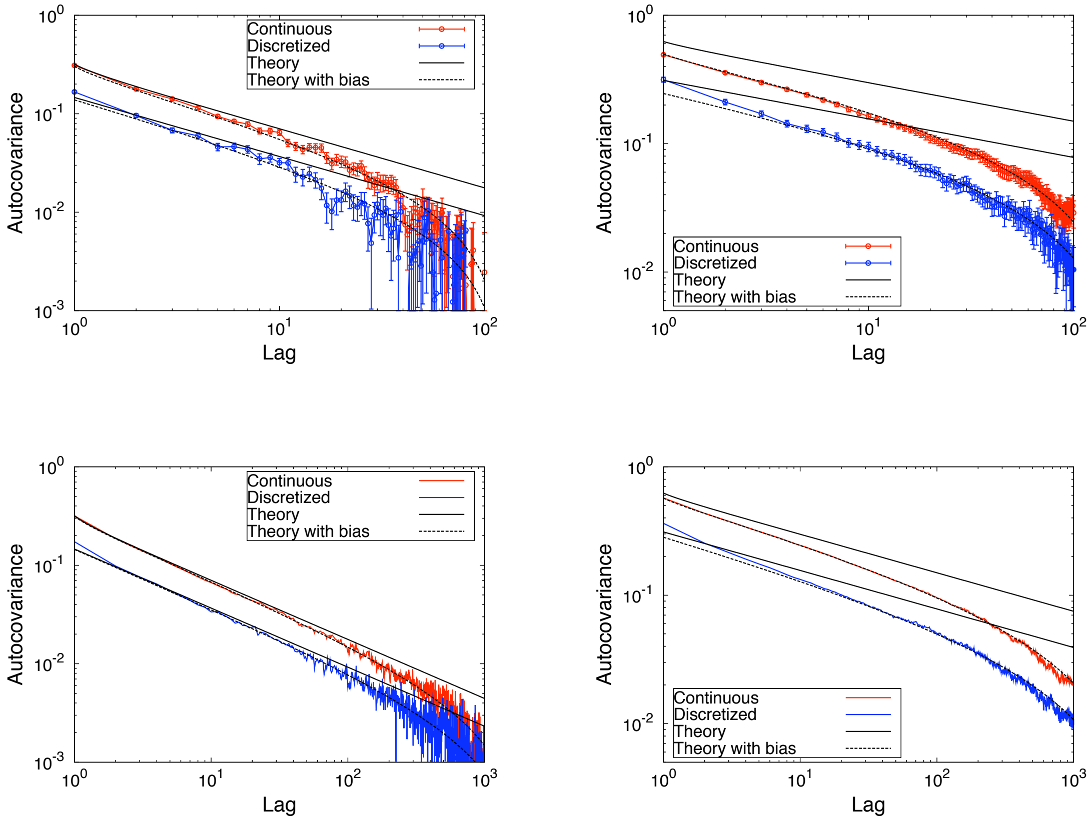

Figure 2: Sample autocovariance of a numerical simulation of a fGn and its discretization with a scaling parameter $\zeta = 0.1$. The time series has length $N = 2^{10}$ (top) and $N = 2^{14}$ (bottom). The Hurst exponent of the fGn is $H = 0.7$ (left) and $H = 0.85$ (right). The figure also shows the asymptotic theoretical autocovariance and the autocovariance corrected for the finite sample bias of (16) both for the fGn and for its discretization.

3.2.1. *Discretized process*

In the case of a discretization with scaling parameter ζ we prove the following proposition:

Proposition 4. *Let $\{x(i)\}_{i\in\mathbb{N}}$ be a discrete time Gaussian weakly stationary process with autocovariance function given by Definition 1. The spectral density $\phi_d(\omega)$ of the discretized process $\{x_d(i)\}_{i\in\mathbb{N}}$ satisfies*

$$\lim_{\omega\to 0^+} \phi_d(\omega) \Big/ \left[\left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 c_\phi |\omega|^{\alpha-1} L(\omega^{-1})\right] = 1 \qquad (19)$$

where $\vartheta_a(u, q)$ is the elliptic theta function, and $c_\phi = \pi^{-1}\Gamma(1-\alpha)\sin(\pi\alpha/2)$.

Moreover, similarly to the case of the autocovariance, second-order corrections to the spectral density are hidden inside the slowly varying function $L(k)$ and the terms we neglected. To compute these corrections explicitly in terms of powers of $|\omega|$ we need to specify a functional form for the

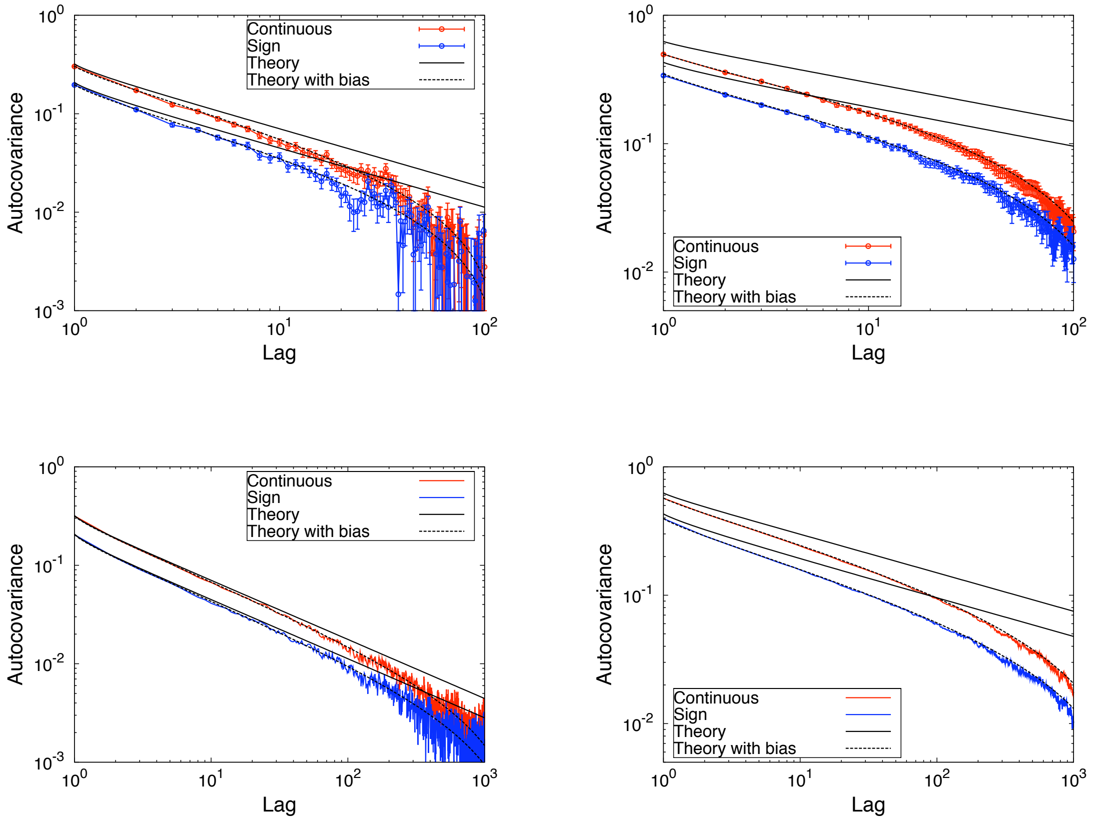

Figure 3: Sample autocovariance of a numerical simulation of a fGn and its sign. The time series has length $N = 2^{10}$ (top) and $N = 2^{14}$ (bottom). The Hurst exponent of the fGn is $H = 0.7$ (left) and $H = 0.85$ (right). The figure also shows the exact theoretical autocovariance and the autocovariance corrected for the finite sample bias of (16) both for the fGn and for its sign.

slowly varying function. We therefore consider long memory processes whose slowly varying function in the autocovariance is well behaved according to Definition 2. We prove the following

Proposition 5. *Let $\{x(i)\}_{i\in\mathbb{N}}$ be a discrete time Gaussian weakly stationary process with autocovariance function given by Definition 1 and $L \in \mathcal{L}(I, b_i, \beta_i)$. We also assume that in Definition 2 either $I < \infty$, or, if $I = \infty$, then $\sup\{\beta\} > 1 - \alpha$. Then, the spectral density $\phi_d(\omega)$ of the discretized process $\{x_d(i)\}_{i\in\mathbb{N}}$ satisfies as $\omega \to 0^+$*

$$\phi_d(\omega) = \left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 c_\phi b_0\, |\omega|^{\alpha-1} \begin{cases} \left(1 + O\left(|\omega|^{\min(2\alpha,\beta_1,1-\alpha)}\right)\right) & if\ \ \alpha+\beta_1 \neq 1, 3\alpha \neq 1 \\ \left(1 + O\left(\max\left(|\omega|^{1-\alpha}\ln|\omega|^{-1}, |\omega|^{2\alpha}\right)\right)\right) & if\ \ \alpha+\beta_1 = 1, 3\alpha \neq 1 \\ \left(1 + O\left(\max\left(|\omega|^{1-\alpha}\ln|\omega|^{-1}, |\omega|^{\beta_1}\right)\right)\right) & if\ \ \alpha+\beta_1 \neq 1, 3\alpha = 1 \\ \left(1 + O\left(|\omega|^{1-\alpha}\ln|\omega|^{-1}\right)\right) & if\ \ \alpha+\beta_1 = 1, 3\alpha = 1 \end{cases} \tag{20}$$

where $\vartheta_a(u, q)$ is the elliptic theta function, and $c_\phi = \pi^{-1}\Gamma(1-\alpha)\sin(\pi\alpha/2)$.

Note that the above expressions do not give exactly the prefactor of the second order correction, but only its order of magnitude. The sign of the prefactor is important to describe the deviation of the spectral density from a pure power law and it is also important to estimate the sign of the bias in the estimation of the Hurst exponent with the periodogram (see Section 4.1.3). By using the results of the asymptotic theory of Fourier transform (see Zygmund (1959)) we are able to compute exactly the prefactor of the second-order correction for $H > 5/6$ (i.e. $\alpha < 1/3$). Unfortunately, for $H < 5/6$ the theory gives us only the order of magnitude.

As we have mentioned above, an important case is given by long memory processes whose slowly varying function is analytical at infinity. This class includes the fGn and the fARIMA process. In these cases the conditions of Proposition 5 hold and we prove the following corollary:

Corollary 2. *If $L \in \mathcal{R}_0$ and L is analytic at infinity, then*

$$\phi_d(\omega) = \left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 c_\phi b_0 \, |\omega|^{\alpha-1} \begin{cases} \left(1 + O\left(|\omega|^{(1-\alpha)}\right)\right) & for \;\; 1/3 < \alpha < 1 \\ \left(1 + O\left(|\omega|^{2/3} \ln |\omega|^{-1}\right)\right) & for \;\; \alpha = 1/3 \\ \left(1 + O\left(|\omega|^{2\alpha}\right)\right) & for \;\; 0 < \alpha < 1/3 \end{cases} \tag{21}$$

where $\vartheta_a(u, q)$ is the elliptic theta function, and $c_\phi = \pi^{-1}\Gamma(1-\alpha)\sin(\alpha\pi/2)$.

3.2.2. Sign process

Similarly to above, we can compute the spectral density of the sign of a Gaussian weakly stationary process.

Proposition 6. *Let $\{x(i)\}_{i\in\mathbb{N}}$ be a discrete time Gaussian weakly stationary process with autocovariance function given by Definition 1. The spectral density $\phi_s(\omega)$ of the sign process $\{sign\,(x(i))\}_{i\in\mathbb{N}}$ satisfies*

$$\lim_{\omega\to 0^+} \phi_s(\omega) / \left[\frac{2}{\pi D} c_\phi \, |\omega|^{\alpha-1} L(\omega^{-1})\right] = 1 \tag{22}$$

where $c_\phi = \pi^{-1}\Gamma(1-\alpha)\sin(\pi\alpha/2)$.

Proposition 7. *Let $\{x(i)\}_{i\in\mathbb{N}}$ be a discrete time Gaussian weakly stationary process with autocovariance function given by Definition 1 and $L \in \mathcal{L}(I, b_i, \beta_i)$. We also assume that in Definition 2 either $I < \infty$, or, if $I = \infty$, then $\sup\{\beta\} > 1-\alpha$. Then, the spectral density $\phi_s(\omega)$ of the sign process $\{sign\,(x(i))\}_{i\in\mathbb{N}}$ satisfies the same equations as the spectral density $\phi_d(\omega)$ of the discretized process $\{x_d(i)\}_{i\in\mathbb{N}}$ in Proposition 5, with $\left(\frac{\vartheta_2(0,e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2$ replaced by $\frac{2}{\pi D}$.*

Corollary 3. *If $L \in \mathcal{R}_0$ and L is analytic at infinity, then the spectral density $\phi_s(\omega)$ satisfies the same equations as the spectral density $\phi_d(\omega)$ in Corollary 2, with $\left(\frac{\vartheta_2(0,e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2$ replaced by $\frac{2}{\pi D}$.*

3.2.3. The spectral density of the discretization of fGn and fARIMA processes

The fGn and the fARIMA process are often used in modeling Gaussian long memory processes. Starting from the explicit functional form of the spectral density of either of these two processes it is direct to show (see Beran (1994)) that the function $L(k)$ is analytical. Moreover, by factoring out the $O(|\omega|^{\alpha-1})$ term, the (relative) second order term of the spectral density is $O(\omega^2)$, which is a very small correction to the leading term of order $O(1)$ even for relatively large frequencies. Hence, roughly speaking, on a log-log plot the spectral density of both the fGn and the fARIMA process is close to a straight line even for relatively large frequencies.

On the other hand, the two corollaries above state that for the discretization (or for the sign) of a Gaussian long memory process with analytical $L(k)$ the relative second order correction to the spectral density around 0^+ is always larger than $O\left(|\omega|^{2/3+\varepsilon}\right)$ for any $\varepsilon > 0$ which is a relatively large correction even for small frequencies. On a log-log plot this leads to a significant deviation from the straight-line behavior (leading term) even for relatively small frequencies. By using the theory of asymptotic Fourier transforms (Zygmund (1959)) we can compute explicitly the prefactor of the second order correction of the spectral density of a discretization of a fGn and of a fARIMA process when $H > 5/6$ (i.e. $\alpha < 1/3$). In both cases we find that the prefactor is positive. As mentioned above, we are not able to compute it analytically when $H < 5/6$. As we will show below, these observations have important consequences for the Hurst exponent estimators based on the periodogram, which is an estimator of the spectral density.

In Figures 4 and 5 we show examples of the sample periodogram of the discretized fGn ($\zeta = 0.1$) and of its sign, respectively, for different time series length and Hurst exponent. As expected, while the periodogram of the fGn is very straight in a log-log scale, the periodogram of the discretized process, as well as the periodogram of the sign process, changes its slope for increasing frequencies. For both the discretized process and the sign process the absolute slope of the periodogram decreases for increasing frequencies, both when $H > 5/6$ and when $H < 5/6$. As we will show in Section 4.1, analytical calculations and numerical simulations indicate that the prefactor of the second order correction is always positive.

4. Estimation of the Hurst exponent

In this section we investigate the estimation of the Hurst exponent from finite time series of the discretized process. We numerically generate time series of discretized long memory processes and we compute the Hurst exponent by using the log-periodogram regression and the DFA. Despite the fact that, as we have demonstrated in the previous sections, the Hurst exponent of the discretized process is the same as the one of the original process, we will show here that both methods give estimates of the Hurst exponent which are systematically and significantly negatively biased.

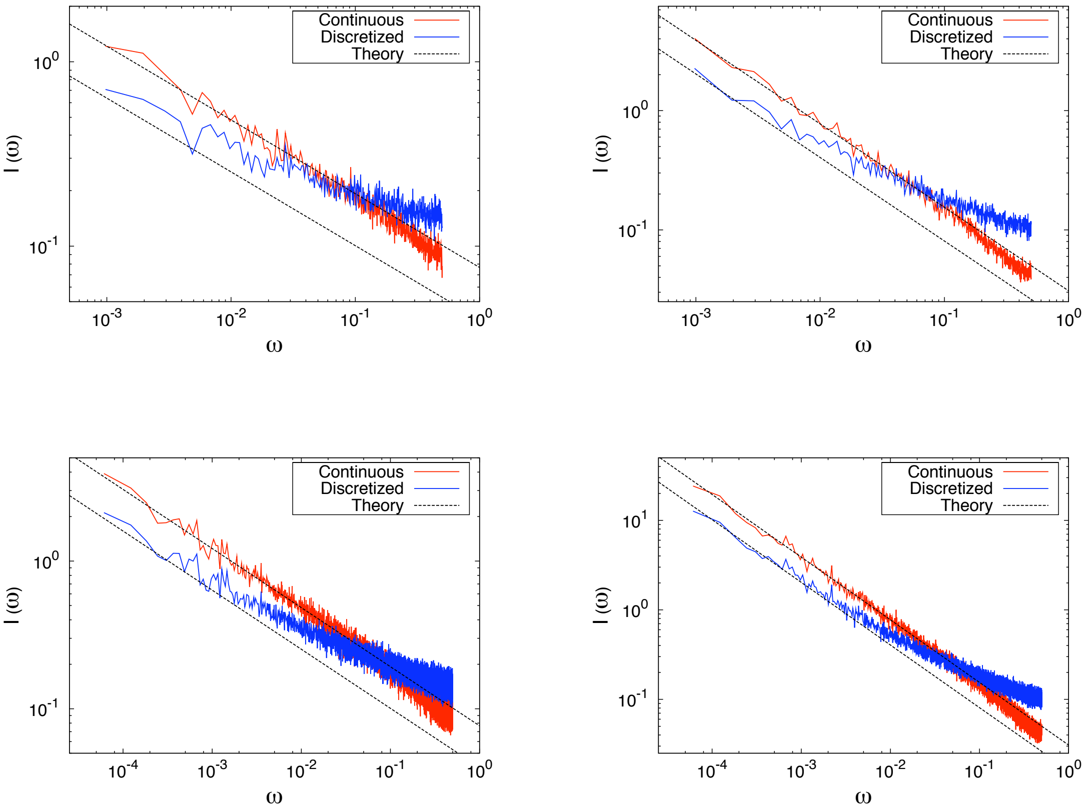

Figure 4: Sample periodogram of a numerical simulation of a fGn and its discretization with a scaling parameter $\zeta = 0.1$. The time series has length $N = 2^{10}$ (top) and $N = 2^{14}$ (bottom). The Hurst exponent of the fGn is $H = 0.7$ (left) and $H = 0.85$ (right). The figure also shows the leading term of the expansion of the spectral density for small ω.

4.1. *Periodogram*

4.1.1. *Definition and notation*

One of the most common estimators of the spectral density is the periodogram. Given a finite time series $x(i)$ with $i = 1, \ldots, N$, the periodogram is

$$I(\omega_j) = \frac{1}{2\pi N} \left| \sum_{k=1}^{N} x(k) e^{i\omega_j k} \right|^2 \qquad j = 1, \ldots, M \tag{23}$$

where $\omega_j = 2\pi j/N$ and M is a positive integer equal to the integer part of $(N-1)/2$.

The spectral density of weakly stationary Gaussian long-memory processes is often rewritten as

$$\phi(\omega) = |1 - e^{-i\omega}|^{-2d} \phi^*(\omega) \tag{24}$$

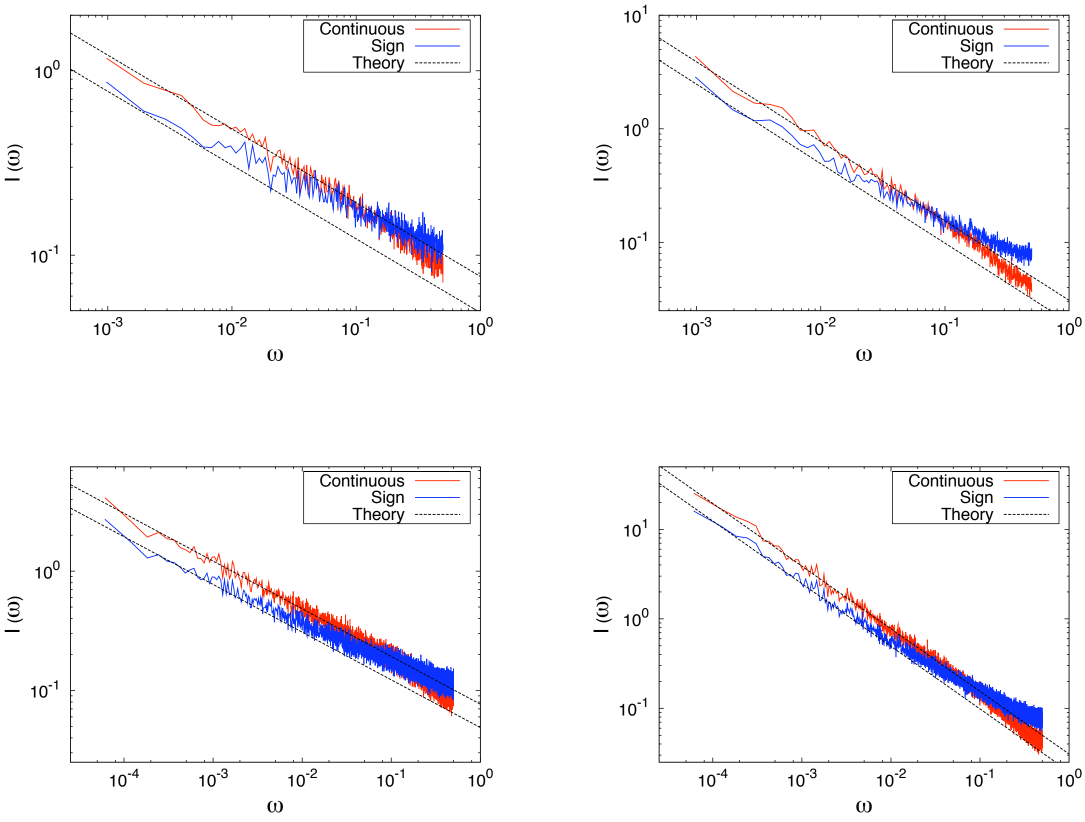

Figure 5: Sample periodogram of a numerical simulation of a fGn and its sign. The time series has length $N = 2^{10}$ (top) and $N = 2^{14}$ (bottom). The Hurst exponent of the fGn is $H = 0.7$ (left) and $H = 0.85$ (right). The figure also shows the leading term of the expansion of the spectral density for small ω.

where $\phi^*(\cdot)$ is an even, positive, continuous function on $[-\pi, \pi]$, bounded above and bounded away from zero. The function ϕ^* determines the high-frequency properties of the series, i.e. the short term correlation structure.

Geweke and Porter-Hudak (1983) (GPH) proposed a semiparametric estimator of d (or H) given by the least squares estimate of the slope parameter of the ordinary linear regression of the first m values of $\log I(\omega_j)$ on the explanatory variable $X_j = \log\left|1 - e^{-i\omega_j}\right| = \log\left|2\sin(\omega_j/2)\right|$. The regression model is

$$\log I(\omega_j) = \log\phi^*(0) - 2dX_j + \log(\phi^*(\omega_j)/\phi^*(0)) + \varepsilon_j \qquad 1 \le j \le m < M \tag{25}$$

where $\varepsilon_j = \log\left(I(\omega_j)/\phi(\omega_j)\right)$. The rationale behind this estimator is based on two assumptions: (i) ε_j are approximately uncorrelated and homoskedastic and (ii) the term $\log(\phi^*(\omega_j)/\phi^*(0))$ is negligible for small $\omega_j \le \omega_m$. From the second assumption it is clear that the choice of m is an important practical problem in the implementation of the GPH estimator. This choice entails a bias-variance tradeoff. Using only the m lowest Fourier frequencies in the regression helps to avoid biases due to the possible non-constancy of $\log\left(\phi^*(\omega_j)/\phi^*(0)\right)$, but increases the variance of the estimate. Geweke and Porter-Hudak suggested the choice of the upper bound $m^{GPH} = N^{1/2}$. They found that this choice gave good results in numerical simulations, but they gave no theoretical basis for this choice.

Agiakloglou, Newbold and Wohar (1993) performed Monte Carlo simulations and showed that the GPH estimator can be badly biased on moderate-sized samples. They argued that the bias is caused by dropping the term $\log\left(\phi^*(\omega_j)/\phi^*(0)\right)$ in the regression model proposed by Geweke and Porter-Hudak.

Moreover, subsequent studies showed that ε_j are asymptotically neither independent nor identically distributed when $N \to \infty$ and j stays fixed (see Künsch (1986), Hurvich and Beltrao (1993), Robinson (1995)). Independently and around the same time, Robinson (1995) and Hurvich and Beltrao (1993) proved that the periodogram $I(\omega_j)$, when evaluated at the Fourier frequencies (which depend on N), suffers from an asymptotic relative bias as an estimator of $\phi(\omega_j)$. Numerical evaluations in Hurvich and Beltro (1993) showed that the asymptotic relative bias is typically positive, monotonically increasing in $|d|$, and monotonically decreasing in j[3]. Thus the asymptotic relative bias is positive and more significant for the first Fourier frequencies, which are the most important frequencies for estimating d. As we will discuss below, the extent to which this bias affects the estimation of the memory parameter depends on the growth rate of m with respect to N. As far as we know, most of the literature only considered either Gaussian processes (Hurvich and Beltrao (1993), Robinson (1995), Hurvich *et al.* (1998)) or linear processes (Velasco (2000)), establishing conditions on m such that the log-periodogram estimate of d is a consistent estimator.

Under Gaussianity assumption Hurvich, Deo, and Brodsky (HDB) (1998) proved consistency and asymptotic normality of the estimator as long as $m \to \infty$ and $N \to \infty$ with $(m \log m)/N \to 0$. Under these and additional regularity conditions, they find the asymptotic optimal choice for m in order to minimize the mean square error of the estimator. The additional regularity conditions are that ϕ^* is bounded above and bounded away from zero, it is three times differentiable with first derivative $\phi^{*\prime}(0) = 0$, and second and third derivatives bounded in a neighborhood of zero. If $\phi^{*\prime\prime}(0) \neq 0$, they proposed the following optimal m

$$m^{HDB} = \left(\frac{27}{128\pi^2}\right)^{1/5} \left(\frac{\phi^*(0)}{\phi^{*\prime\prime}(0)}\right)^{2/5} N^{4/5} \tag{26}$$

Hurvich *et al.* (1998) considered fARIMA processes, which satisfy these regularity conditions. However, for example, the optimal m^{HDB} is not defined for a fARIMA$(0, d, 0)$ process, because for this process $\phi^{*\prime\prime}(0) = 0$. Moreover, these regularity conditions are quite restrictive. The fGn, for example, does not satisfy them[4].

---

[3] The only exception is a small closed interval around $d = 0$ where asymptotic relative bias is slightly smaller than unity, and for fixed d it is decreasing in j. In any case, negative asymptotic relative bias, when it does occur, is of such a small magnitude that it would be of negligible consequence in practice.

[4] In fact, it is easy to show that for the fGn $\phi^*(\omega) = 1 + c_1\omega^2 + c_2\omega^{2(1+d)} + O\left(\omega^{3+2d}\right)$, where $c_1 < 0$ and $c_2 > 0$. The third derivative of this function is not uniformly bounded in a neighborhood of zero, because of the term $\omega^{2(1+d)}$.

We are concerned here with the periodogram estimation of the Hurst exponent of the discretized process which is neither Gaussian nor linear. Therefore our processes do not satisfy the assumptions of Hurvich *et al.* (1998) because they are non-Gaussian and because, as we show below, ϕ^* of the discretized process does not satisfy the HDB regularity conditions. For these reasons, in the following numerical simulations we take different values of the threshold, namely $m = N^{1/2}, N^{3/5}, N^{4/5}$. In other words, we consider the GPH and the HDB threshold (even if there is no theoretical justification) and an intermediate threshold.

4.1.2. Numerical simulations

We numerically generated the Gaussian process as a fGn and we considered two values of the Hurst exponent, namely $H = 0.7$ and 0.85. This choice of Hurst exponents is motivated by the need to have values below and above the critical value $H = 5/6$. In order to test the dependence on the time series length we considered series of length $N = 2^{10}$ and $N = 2^{14}$. We then applied four discretization procedures corresponding to discretization parameter $\zeta = 0.1, 0.25, 0.5$ and the sign of the process. We performed $L = 10^3$ simulations in order to obtain the statistical properties of the estimators.

The results of the estimation over the $L = 10^3$ simulations are summarized in Tables 1 and 2. The tables show the mean, standard error, and three quantiles (2.5%, 50%, and 97.5%) of the estimator $\widehat{H}$ of the Hurst exponent obtained by using the Geweke-Porter Hudak regression (25) with the three thresholds, namely $m = N^{1/2}$, $N^{3/5}$ and $N^{4/5}$.

For the continuous process, the periodogram has a positive asymptotic relative bias as estimator of the spectral density and this bias is monotonically decreasing in j (Künsch (1986), Hurvich and Beltrao (1993), Robinson (1995)). In our results this is evident from the slight overestimation of H for the continuous process with both $N = 2^{10}$ and $N = 2^{14}$, especially for $m = N^{4/5}$. For the discretized process we observe that the negative bias due to the discretization increases with m, as expected by Proposition 8 (see below). The GPH estimator ($m = N^{1/2}$) is less biased by discretization than the estimator with threshold $m = N^{4/5}$. However, as pointed out in Hurvich *et al.* (1998), the GPH estimate has a large dispersion and is very noisy. These properties are somewhat expected from the bias variance tradeoff. Looking more carefully at the estimators with $m = N^{3/5}$ and $m = N^{4/5}$ we observe that for all values of N and H, $\widehat{H}$ of the discretized series is significantly negatively biased. Specifically, when $H = 0.7$ we observe a severe underestimation of the Hurst exponent for the sign and for $\zeta = 0.1$. When $H = 0.85$ we observe a severe underestimation of the Hurst exponent for the sign and for $\zeta = 0.1, 0.25$. This problem is still evident for long time series. Obviously, in this case the standard error declines, but the finite sample negative bias is not significantly reduced. For example, for $m = N^{4/5}$ and $N = 2^{14}$ the 97.5% quantile is smaller than (or approximately equal to) the true H for the sign and for $\zeta = 0.1, 0.25$, both for $H = 0.7$ and for $H = 0.85$. We also note that the effect of the bias due to the discretization is increasing with the long memory parameter, i.e. the larger is H, the larger is the discretization bias. Finally, note that the bias is a finite size effect.

We ran the same simulations for a fARIMA$(0, d, 0)$, and we got similar results.

Table 1: Estimation of the Hurst exponent of a fGN with $H = 0.7$ and its discretization with the sign function and with $\zeta = 0.1, 0.25$, and 0.5. The time series has length 2^{10} (top) and 2^{14} (bottom). The estimation of the Hurst exponent is performed with the periodogram by using thresholds $m = N^{1/2}$, $m = N^{3/5}$, and $m = N^{4/5}$ (see text). The table reports the mean value of the estimator $\widehat{H}$ over 10^3 numerical simulations, together with the standard error and the 2.5%, 50%, and 97.5% percentile.

4.1.3. The bias of the log-periodogram estimator of H for the discretized process

We give now some theoretical arguments that helps understanding the possible origin of estimation biases and their sign when the regression of the periodogram is used to estimate the Hurst exponent of the discretized process.

We follow here the notation of Hurvich *et al.* (1998). Let $\hat{d}$ be the log-periodogram regression estimate of the true long memory parameter d. We know that

$$\hat{d} - d = -\frac{1}{2S_{xx}} \sum_{j=1}^{m} a_j \log \phi_j^* - \frac{1}{2S_{xx}} \sum_{j=1}^{m} a_j \varepsilon_j$$

The estimation of the Hurst exponent is performed with the periodogram by using thresholds $m = N^{1/2}$, $m = N^{3/5}$, and $m = N^{4/5}$ (see text). The table reports the mean value of the estimator $\widehat{H}$ over 10^3 numerical simulations, together with the standard error and the 2.5%, 50%, and 97.5% percentile.

where $\phi^*_j = \phi^*(\omega_j)$, $a_j = X_j - \frac{1}{m}\sum_{k=1}^{m} X_k$ and $S_{xx} = \sum_{k=1}^{m} a_k^2$. Consequently, the bias of $\hat{d}$ is given by

$$\mathbb{E}[\hat{d} - d] = -\frac{1}{2S_{xx}} \sum_{j=1}^{m} a_j \log \phi^*_j - \frac{1}{2S_{xx}} \sum_{j=1}^{m} a_j \mathbb{E}[\varepsilon_j] \,. \tag{27}$$

This expression shows that the bias is the sum of a contribution coming from the high frequency components of the spectral density and a contribution coming from the error terms ε_j.

Hurvich *et al.* (1998) considered a generic Gaussian long memory process satisfying the regularity conditions that $\phi^{*\prime}(0) = 0$, $|\phi^{*\prime\prime}(\omega)| < \widetilde{B}_2 < \infty$, and $|\phi^{*\prime\prime\prime}(\omega)| < \widetilde{B}_3 < \infty$ for all ω in a neighborhood of zero. In the limit $m \to \infty$, $N \to \infty$, with $m/N \to 0$ and $(m \log m)/N \to 0$ they proved that

$$-\frac{1}{2S_{xx}}\sum_{j=1}^{m} a_j \log\phi^*_j = \frac{-2\pi^2}{9}\frac{\phi^{*\prime\prime}(0)}{\phi^*(0)}\frac{m^2}{N^2} + o\left(\frac{m^2}{N^2}\right). \tag{28}$$

This expression gives the bias due to high frequency components of the spectral density. It is possible to show that the above result holds also for a generic non-Gaussian process satisfying the Hurvich *et al.* regularity conditions.

However, this result does not hold for the discretized process. In fact from Proposition 5 we know that that, for example, when $\alpha_1 + \beta_1 \neq 1$ and $3\alpha \neq 1$ (case (i) of Proposition 5) we have

$$\phi^*_d(\omega_j) = C\left(1 + O\left(|\omega_j|^{\min(2\alpha,\beta_1,1-\alpha)}\right)\right) \tag{29}$$

Because $\min(2\alpha,\beta_1,1-\alpha) < 1$, the first derivative of ϕ^*_d does not even exist in $\omega = 0$, and both the left- and the right-derivative are unbounded in a neighborhood of zero. Obviously, this is true also for all the higher-order derivatives.

Here we generalize the above result of Hurvich *et al.* (1998) to the discretized process by proving the following proposition:

Proposition 8. *Under the conditions of Proposition 5 case(i), let* $\underline{\alpha} = \min(2\alpha,\beta_1,1-\alpha)$ *and* C *the pre-factor in front of the second-order correction. Let* $\varepsilon > 0$ *s.t. the third-order correction to spectral density of the discretized process is* $O(\omega^{\underline{\alpha}+\varepsilon})$*. Assume that* $m \to \infty$, $N \to \infty$, *with* $m/N \to 0$ *and* $(m^{\min(\underline{\alpha},\varepsilon)}\log m)/N^{\min(\underline{\alpha},\varepsilon)} \to 0$. *Then,*

$$-\frac{1}{2S_{xx}}\sum_{j=1}^{m} a_j \log\phi^*_d(\omega_j) = -\frac{C\underline{\alpha}(2\pi)^{\underline{\alpha}}}{2(1+\underline{\alpha})^2}\frac{m^{\underline{\alpha}}}{N^{\underline{\alpha}}} + o\left(\frac{m^{\underline{\alpha}}}{N^{\underline{\alpha}}}\right) \tag{30}$$

Similar considerations and a straightforward extension of this proposition can be obtained for the other cases of Proposition 5. The proof of this and of the other propositions and theorems in this section are in Appendix C.

Let us restrict now our attention to the discretization of a fGn or of a fARIMA$(0,d,0)$ process. This proposition shows that the bias due to $\log(\phi^*(\omega_j)/\phi^*(0))$ is much larger for the discretized process than for the original process. In fact the rate of decay of the bias as $m, N \to \infty$ is much smaller for the discretized process ($(m/N)^{\underline{\alpha}}$) than for the original process ($(m/N)^2$). Moreover, the discretized process needs a stricter trimming condition ($(m^{\min(\underline{\alpha},\varepsilon)}\log m)/N^{\min(\underline{\alpha},\varepsilon)} \to 0$) than the original process ($(m\log m)/N \to 0$). We also mentioned above that for a fGn or for a fARIMA$(0,d,0)$ process the prefactor C of the second order correction of the spectral density is positive when $H > 5/6$. This means that in this regime the bias due to the high frequency components is negative. For $H < 5/6$ we are not able to compute the sign of C. However, from our Monte Carlo simulations we observe that the log spectral density is strongly upward sloping at high frequencies for both $H > 5/6$ and $H < 5/6$. This suggests that the prefactor C is positive for all H. From these empirical observations and from Proposition 8, we conjecture that the bias due to the high frequency components is negative for all H.

The total bias on d has also a contribution due to the errors ε_j. Under Gaussianity Robinson (1995) and Hurvich *et al.* (1998) proved that $\mathbb{E}[\varepsilon_j] = O(\log j/j)$. Velasco (2000) in the proof of his

Theorem 1 obtained similar results under the assumption that the process is linear[5]. However, the discretized process is neither Gaussian nor linear and thus we cannot use these results. Moreover, we do not have an estimation of the second term in the right hand side of (27). From Jensen's inequality we have $\mathbb{E}[\varepsilon_j] \leq \log \mathbb{E}\left[I(\omega_j)/\phi(\omega_j)\right]$, and from Hurvich and Beltrao (1993) and Robinson (1995) we know that asymptotically $\mathbb{E}\left[I(\omega_j)/\phi(\omega_j)\right]$ is strictly greater than 1. Therefore, the bias due to ε_j may be either positive or negative. This will depend on the distribution function of ε_j, which is nontrivial for the discretized process. For these reasons we infer the behavior of the second term from the numerical simulations.

In the previous section we have seen that simulations show that the periodogram estimator of d is negatively biased. Note that this is different from the Gaussian case (see for example Agiakloglou *et al.* (1993)) where the periodogram is positively biased. From this empirical observation we can make two possible conjectures. Either the bias due to ε_j is also negative and thus the total bias is also negative, or the bias due to ε_j is positive but in absolute value smaller than the (negative) bias of the high frequency components, and thus the total bias is negative as observed in numerical simulations.

More in depth analyses are needed to clarify this point. Our proposition 8 gives a bound of the high frequency component of the bias and shows that it slowly decays to zero. This means that it likely has an important role in the total bias of the periodogram.

4.2. Detrended Fluctuation Analysis

4.2.1. Definition and notation

We now consider the Detrended Fluctuation Analysis (DFA) (see Peng *et al.* (1994)), a method to investigate the properties of a long memory process and to estimate the Hurst exponent. This method was introduced more than fifteen years ago to investigate physiological data, in particular the heartbeat signal. Since its introduction it has been applied to a large variety of systems, including physical, biological, economic, and technological data. The idea is to consider the integrated process and detrend it locally. The scaling of the fluctuations of the residuals as a function of the box size in which the regression is performed gives the estimate of the Hurst exponent. More precisely, let $\{x(1), \ldots x(N)\}$ be a finite time series and denote the discrete integration of this sample as

$$y(k) = \sum_{i=1}^{k} x(i) \tag{31}$$

The integrated time series is divided into $[N/m]$ boxes of equal length m, where $[z]$ is the integer part of z. For $j \in \{1, \ldots, [N/m]\}$, let us define the vector:

$$y^{(j)} = (y(1 + m(j-1)), \ldots, y(mj))' \tag{32}$$

In each box, a least squares line is fit to the data (representing the trend in that box). The y coordinate of the straight line segments is denoted by $y_m(k)$. Next, one detrends the integrated time series, $y(k)$, by subtracting the local trend, $\widehat{y}_m(k)$, in each box. The root-mean-square fluctuation of this integrated and detrended time series is calculated by

---

[5] Note, however, that Velasco considered the pooled log-periodogram.

$$F(m) = \sqrt{\frac{1}{m \cdot [N/m]} \sum_{k=1}^{m \cdot [N/m]} [y(k) - \widehat{y}_m(k)]^2}. \tag{33}$$

This computation is repeated over all time scales (box sizes) to characterize the relationship between $F(m)$ and the box size m. Typically $F(m)$ increases with box size m. For a long memory process the Hurst exponent is given by the relation $F(m) \propto m^H$. Therefore H is estimated by performing a log-regression of $F(m)$ versus m. The proposers of this method claim that DFA is able to perform well also in the presence of non-stationarities, such as trends, (see Peng *et al.* (1994)), even if some recent results dispute this claim (see Bardet and Kammoun (2008)).

The partial DFA function computed in the j-th window of size m is

$$F_j^2(m) = \frac{1}{m} \sum_{i=m(j-1)+1}^{mj} (y(i) - \widehat{y}_m(i))^2 \tag{34}$$

for $j \in \{1, \ldots, [N/m]\}$. Then, we can write

$$F^2(m) = \frac{1}{[N/m]} \sum_{j=1}^{[N/m]} F_j^2(m) \tag{35}$$

Recently, Bardet and Kammoun (2008) (Lemma 2.2) showed that for a stationary process the series $\{F_j(m)\}_{1 \le j \le [N/m]}$ is a stationary process for all m. This means that in order to study the asymptotic statistical properties of the DFA we can focus on $F_1^2(m)$ only. They then used this result to provide an asymptotic expression (Theorem 4.2) for $\mathbb{E}\left[F_1^2(m)\right]$ for a general class of Gaussian long memory processes. Here we extend this result to non-Gaussian long memory processes (see Theorem 1 below). In doing that we show that the order of the correction of the asymptotic expansion given in Bardet and Kammoun (2008) for generic Gaussian processes (Theorem 4.2) is incorrect and we provide the correct order. For the special case of fGN and fARIMA the result provided in Bardet and Kammoun (2008) is correct because of the cancellation of the prefactor of the correction term observed for a generic long memory process.

4.2.2. A theorem on the detrended fluctuation analysis of a general long memory process

Here we generalize Theorem 4.2 of Bardet and Kammoun (2008) to a general class of non-Gaussian long memory processes. The discretized process belongs to this class.

We prove the following:

Theorem 1. *Let $\{x(i)\}_{i \in \mathbb{N}}$ be a weakly stationary long memory process, with zero mean, finite variance, and the following autocovariance function*

$$\gamma(k) = Ak^{2H-2}\left(1 + O\left(k^{-\beta}\right)\right) \quad for \;\; k \to \infty, \tag{36}$$

with $A > 0$, $1/2 < H < 1$, and $\beta > 0$. Then,

$$\mathbb{E}\left[F_1^2(m)\right] = D' f(H) m^{2H} \begin{cases} \left(1 + O\left(m^{-\min(2H-1,\beta)}\right)\right) & if \;\; \beta \neq 2H-1 \\ \left(1 + O\left(m^{1-2H}\ln m\right)\right) & if \;\; \beta = 2H-1 \end{cases} \tag{37}$$

where $D' = \frac{A}{H(2H-1)}$, and $f(H) = \frac{1-H}{(1+H)(2+H)(1+2H)}$.

First of all, note that the class of processes for which one can apply this theorem is more general of those of Definition 2, but clearly less general than those of Definition 1. Second, our theorem gives a different order of the correction compared to the one given in Theorem 4.2 of Bardet and Kammoun (2008). In fact, Bardet and Kammoun give $O(m^{-\min(1,\beta)})$, while our theorem gives $O(m^{-\min(2H-1,\beta)})$. In many cases of interest (for example when $\beta > 1$) the leading error term is $O(1/m^{2H-1})$ rather than $O(1/m)$ as stated in Bardet and Kammoun (2008).

For fGn or fARIMA$(0, d, 0)$ we observe a specific behavior. In fact, in these cases the error term is $O(m^{-1})$, instead of $O(m^{-\min(2H-1,\beta)})$, because the prefactor of the terms of order $O(m^{1-2H})$ cancels out exactly, and $\beta = 2$. This depends on the specific functional form of the autocovariance of these processes. Therefore, as stated in Bardet and Kammoun (2008), Property 3.1. we have:

Corollary 4. *For a fractional Gaussian noise (fGn) it is*

$$\mathbb{E}\left[F_1^2(m)\right] = D f(H) m^{2H}(1 + O(m^{-1})) \tag{38}$$

The general Theorem 1 gives the asymptotic properties of the fluctuation function for a time series obtained by discretizing or taking the sign of a Gaussian process. The root mean square fluctuations for discretized processes are given by the following two corollaries

Corollary 5. *For the discretized process of a Gaussian time series with the properties of Theorem 1 it is*

$$\mathbb{E}\left[F_1^2(m)\right] = \left(\frac{\vartheta_2(0, e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 D' f(H) m^{2H} \begin{cases} \left(1 + O\left(m^{1-2H}\right)\right) & if \;\; 1/2 < H < 5/6 \\ \left(1 + O\left(m^{-2/3}\ln m\right)\right) & if \;\; H = 5/6 \\ \left(1 + O\left(m^{4H-4}\right)\right) & if \;\; 5/6 < H < 1 \end{cases} \tag{39}$$

where $\vartheta_a(u, q)$ is the elliptic theta function, and D' and $f(H)$ are defined as in Theorem 1.

Corollary 6. *For the sign of a Gaussian time series with the properties of Theorem 1 $\mathbb{E}\left[F_1^2(m)\right]$ satisfies the same equations as in Corollary 5, with $\left(\frac{\vartheta_2(0,e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2$ replaced by $\frac{2}{\pi D}$.*

4.2.3. Numerical simulations

We then considered the performance of the DFA as an estimator of the Hurst exponent on finite time series. We considered the same parameters as in the analysis of the performance of the log-periodogram regression. Hence we discretized a fGn with $H = 0.7$ and 0.85 and we generated $L = 10^3$ time series of length $N = 2^{10}$ and 2^{14}. We then applied four discretization procedures corresponding to discretization parameter $\zeta = 0.1, 0.25, 0.5$ and the we considered the sign of the process. Following a standard practice, we consider values of m ranging from $m = 4$ to $m = N/4$.

Figures 6 and 7 show an example of the root mean square fluctuation $F(m)$ as a function of the block size m. As in the case of the periodogram, a different behavior is observed for the Gaussian process and for its discretization. For the former $F(m)$ is well described by a power law with exponent H over the whole range of investigated block sizes m. On the contrary, for the discretized (or sign) process, $F(m)$ changes significantly slope in the log-log scale, i.e. it has a varying local power law behavior. Only for large box sizes the function $F(m)$ converges to the expected asymptotic behavior from above. This again suggest a significant negative bias in the estimation of H on finite samples, bias that we quantitatively observe in estimation below. In fact, in order to estimate the Hurst exponent through DFA one needs to perform a best fit of F with a power law function. The ambiguity is however the interval of values of m where one performs the fit. To the best of our knowledge there is no rule for selecting optimally such an interval. One expects to obtain a less biased, but noisier, estimate of H by performing the fit in a small region corresponding to large values of the block size m. To investigate this point we estimate the Hurst exponent by performing the fit over a fraction q of the largest values of $\log_{10}[m]$. We consider three values of q, namely $q = 1$ (the whole interval), $q = 0.5$ (the largest half), and $q = 0.25$ (the largest quartile).

The results of our analysis are summarized in Table 3 and 4. When $q = 1$ we observe an underestimation of $\widehat{H}$ for the discretized series. This underestimation is always significant in terms of standard errors. Specifically, when $N = 2^{10}$ there is a severe underestimation for the sign and for $\zeta = 0.1, 0.25$, both when $H = 0.7$ and when $H = 0.85$. For long series ($N = 2^{14}$) we observe a severe underestimation for the sign and for $\zeta = 0.1$, both when $H = 0.7$ and when $H = 0.85$. Note that for $N = 2^{14}$ the 97.5% quantile of $\widehat{H}$ is smaller than the true value of H for the sign and for $\zeta = 0.1$, both when $H = 0.7$ and when $H = 0.85$. By changing q we observe similar results. For short samples the DFA estimate with $q = 1$ performs better than that with $q = 0.25$. This might be due both to the fact that points corresponding to large m are very noisy and to the fact that the fluctuation function converges to its asymptotic value from above. Finally, note that for the discretized process is not always true that the less biased estimator is obtained for small values of q. In fact, in most of the cases we observe quite the contrary. This might be due to the shape of the root mean square fluctuation function F that changes slowly slope when the block size m varies (see Figures 6 and 7).

4.3. Discussion on the estimation of the Hurst exponent of a discretized process

In conclusion our analytical considerations and numerical simulations show that both the log-periodogram regression and the DFA consistently give negatively biased estimates of the Hurst exponent H (or of the fractional differencing parameter d) when they are applied to discretized processes. This is in contrast with what happens when the log-periodogram regression is used to estimate the Hurst exponent of a Gaussian process. In fact, a large body of literature showed that for Gaussian processes the log-periodogram regression gives a positively biased estimate of the Hurst exponent. Our results show also that the size of the negative bias of $\widehat{H}$ for a discretized process can be significant due to the fact that the second order correction of the spectral density or of the root mean square fluctuation F of the DFA is large for a discretized process. Table 4: Estimation of the Hurst exponent of a fGN with $H = 0.85$ and its discretization with the sign function and with $\zeta = 0.1$, 0.25, and 0.5. The time series has length 2^{10} (top) and 2^{14} (bottom). The estimation of the Hurst exponent is obtained with the Detrended Fluctuation Analysis by performing the least square regression over a q fraction of the largest values of $\log_{10}[m]$ (see text). The table reports the mean value of the estimator $\widehat{H}$ over 10^3 numerical simulations, together with the standard error and the 2.5%, 50%, and 97.5% percentile.

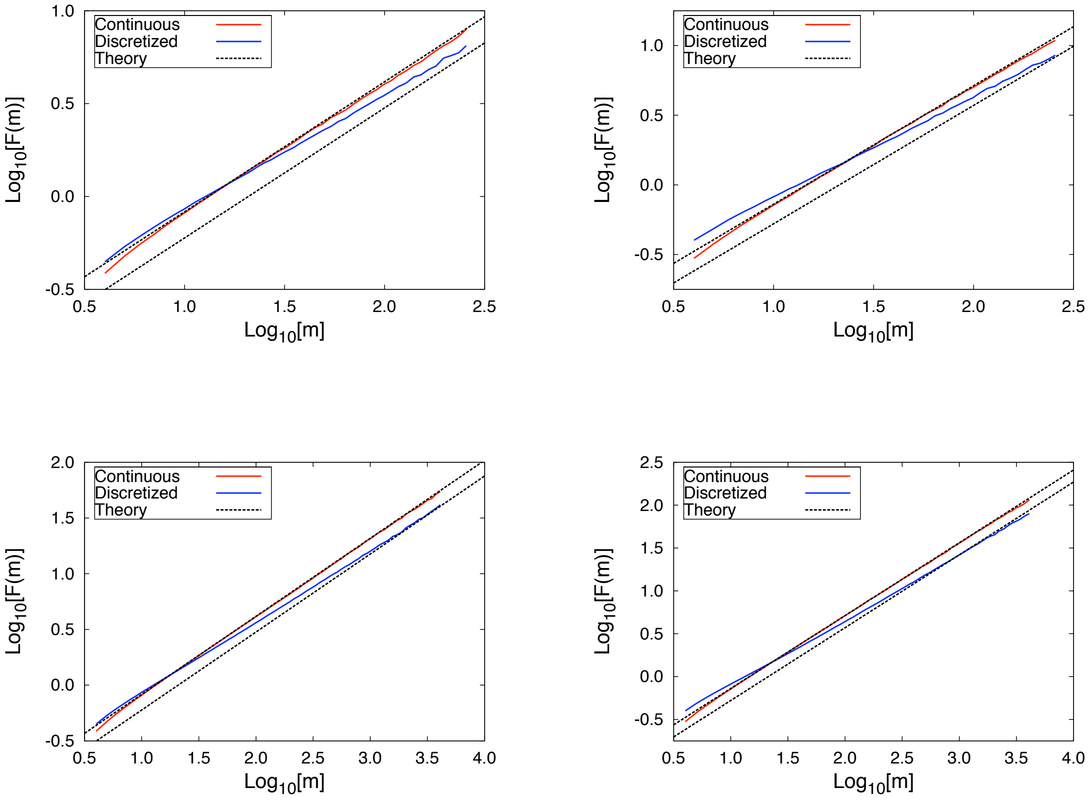

Figure 6: Root mean square fluctuation $F(m)$ as a function of the block size m of a numerical simulation of a fGn and its discretization with a scaling parameter $\zeta = 0.1$. The time series has length $N = 2^{10}$ (top) and $N = 2^{14}$ (bottom). The Hurst exponent of the fGn is $H = 0.7$ (left) and $H = 0.85$ (right). The figure also shows the leading term of the expansion of the $F(m)$ for large m (dashed lines).

bias can be partly overcome by taking small values of m (for the log-periodogram regression) or small intervals for the fit of the root mean square fluctuations (for the DFA). However, in both cases the variance of the estimators become large and thus the estimator is not significantly reliable.

When we compare the log-periodogram regression and the DFA we find that in terms of bias the best estimator of H is the log-periodogram with GPH threshold. The DFA estimator is very sensitive to the window chosen for the regression. The plot of the root mean square fluctuation might help in determining a suitable window, but the choice seems quite arbitrary and thus this method is more suited for an exploratory analysis.

Despite the fact that we have presented results only for the fGn and fARIMA$(0, d, 0)$ processes, we have also run extensive Monte Carlo simulations for stationary fARIMA$(1, d, 0)$ and fARIMA$(0, d, 1)$ processes. The results are similar to those obtained for fGn and fARIMA$(0, d, 0)$, with a statistically significant underestimation of the Hurst exponent for the sign process and for coarse discretizations, both for the log-periodogram regression and for the DFA method. However,

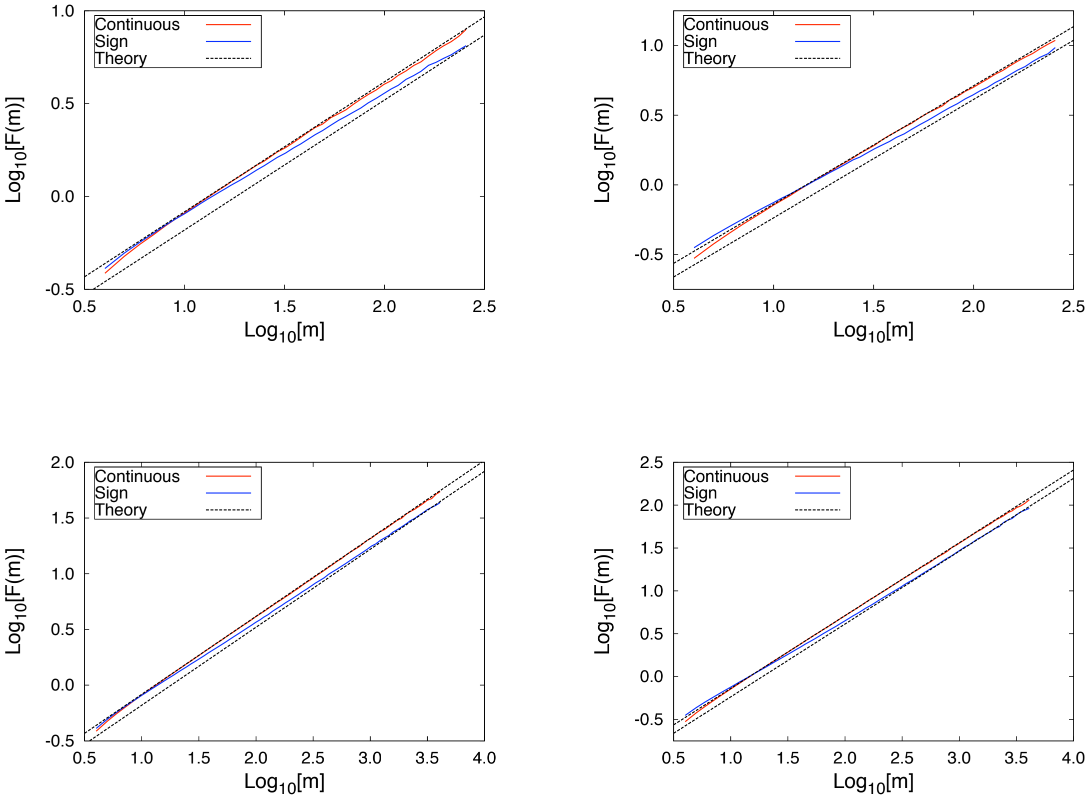

Figure 7: Root mean square fluctuation $F(m)$ as a function of the block size m of a numerical simulation of a fGn and its sign. The time series has length $N = 2^{10}$ (top) and $N = 2^{14}$ (bottom). The Hurst exponent of the fGn is $H = 0.7$ (left) and $H = 0.85$ (right). The figure also shows the leading term of the expansion of the $F(m)$ for large m (dashed lines).

for stationary fARIMA$(1, d, 0)$ and fARIMA$(0, d, 1)$ the size of the underestimation depends on the high-frequency behavior of the spectral density of the original process. If the coefficient of the characteristic polynomial is positive, the size of the underestimation is smaller than for fGN and fARIMA$(0, d, 0)$. If the coefficient of the characteristic polynomial is negative, the size of the underestimation is larger than for fGN and fARIMA$(0, d, 0)$. In terms of log-periodogram regression these results are intuitive. In fact, when we estimate the Hurst exponent of the continuous-valued fARIMA$(1, d, 0)$ or fARIMA$(0, d, 1)$ process, if the coefficient of the characteristic polynomial is positive, the bias due to the high-frequency component of the spectral density is positive. On the other hand, if the coefficient of the characteristic polynomial is negative, the bias due to the high-frequency component of the spectral density is negative. When we consider the discretized (or the sign) process these biases combine with the effect of the discretization, which is negative. Therefore, if the coefficient is positive the two effects have opposite signs and the total bias on the estimate of the Hurst exponent is smaller. On the other hand, if the coefficient is negative the two effects have the same sign and the total bias on the estimate of the Hurst exponent is larger. For the sake of brevity, we do not report these results here, but they are available from the authors by request.

5. Discussion and concluding remarks

5.1. Relation to the measurement error literature

As mentioned in the introduction, round-off error can be considered a form of measurement error, even if the type of measurement error typically considered in the literature is different, being modeled as a white noise uncorrelated with the latent process. On the other hand, the round-off error is a deterministic function of the latent process itself, and it is neither uncorrelated with the latent process nor a white noise.

Recently, in the context of short-memory processes, Hansen and Lunde (2010) have studied the effect of sampling errors on the dynamic properties of an underlying ARMA(p, q) time series. They have proved that the estimates of both the persistence parameter and the autocorrelation function are negatively biased by the measurement error. Our paper contributes in this direction for the case of long-memory processes subject to round-off errors. In fact, we are able to compute exactly the asymptotic scaling factor between the autocorrelation function of the realized process and that of the latent process. This scaling factor is a function only of the adimensional parameter ζ, which in turn depends on the grid size (δ) and the variance of the underlying series (D). In most cases of interest the researcher knows the level of discretization. In principle, if the researcher knew also the variance of the underlying process, then she could estimate the autocorrelation function of the latent variable exactly for large lags. The same holds true for the spectral density at small frequencies and the root mean square fluctuation function for large box sizes. In general, however, the variance of the underlying process is not known *ex ante*, and the researcher needs to make inference on it. Even if the problem of the inference on ζ (or D) is outside the scope of this paper, it is worth mentioning that by considering the fraction q_0 of points of the discretized process with value zero it is possible to infer the value of the variance of the underlying process. In fact, we showed that $q_0 = erf[\delta/2\sqrt{2D}]$ and therefore the knowledge of the grid size δ and the measurement of q_0 allow to infer D. Finally, note that other methods could be used to estimate D, such as, for example, by comparing the autocovariance of the discretized process with two different values of ζ.

In the context of long memory processes, Hurvich, Moulines, and Soulier (2005) considered a process that can be decomposed into the sum of a long memory signal (possibly non-stationary) and a white noise, possibly contemporaneously correlated with the signal. They proved that the observed series has the same Hurst exponent as the underlying signal, and from numerical simulations observed that standard estimators of the Hurst exponent, such as the GPH estimator, suffer from a negative bias. Hurvich, Moulines, and Soulier (2005) proposed a corrected local Whittle estimator, which is unbiased, but has larger asymptotic standard errors. Recently Rossi and Santucci de Magistris (2011) analyzed the effect of measurement errors on the estimation of the Hurst exponent. Specifically, they studied the effect of measurement errors on the estimation of the dynamic properties of the realized variance, as an *ex-post* estimator of the integrated variance. Rossi and Santucci de Magistris (2011) find that discrete frequency sampling and market microstructure noise induce a finite-sample bias in the fractionally integration semiparametric estimates. Based on Hurvich, Moulines, and Soulier (2005) they propose an unbiased local Whittle estimator (with larger asymptotic standard errors) that accounts for the presence of the measurement error. However, the corrected Whittle estimator proposed by Hurvich, Moulines, and Soulier (2005) and Rossi and Santucci de Magistris (2011) does not apply to the round-off error, because the round-off error does not satisfy the standard assumptions on the measurement error. More recently, in a working paper, Corsi and Renò (2011) proposed an indirect inference approach to estimate the long memory parameter of a latent integrated volatility series.

Our paper contributes to this literature by providing the second order term of the spectral density and of the root mean square function for the discretized process. A possible extension is to identify analytically and numerically the asymptotic region over which the bias on the long memory estimates due to these second order corrections becomes negligible. From Proposition 8 we know the order of magnitude of the bias on the log-periodogram regression estimate due to the high frequency component. A possible extension is to estimate also the bias due to the noise term of the regression (see Section 4.1), and then to find a suitable threshold m of Fourier frequencies to use in the regression in terms of bias reduction. Similarly, one could use our results on the second order correction to the root mean square fluctuation to estimate a suitable threshold q for the DFA regression (see Section 4.2) in terms of bias reduction. This is outside the scope of the present paper and is left as future work.

5.2. Concluding remarks

We have presented an extensive analytical and numerical investigation of the properties of a continuously valued long memory process subject to round-off error. We have shown that the discretized process is also long memory with the same Hurst exponent as the latent process. We have explicitly computed the leading term of the asymptotic expansion of the autocovariance function, of the spectral density for small frequencies, and of the root mean square fluctuation for large box sizes. We have shown that the autocovariance, the spectral density and the root mean square fluctuation are asymptotically rescaled by a factor smaller than one, and we have computed exactly this scaling factor. More important in all three cases we have computed the order of magnitude the second order correction. This term is important to quantify the bias of the Hurst exponent estimators based on these quantities. An in depth analysis of Hurst exponent estimators, namely the periodogram and the Detrended Fluctuation Analysis, shows that both the estimators are significantly negatively biased as a consequence of the order of magnitude of the second order corrections.

These results can be considered the starting point for several future research directions. A first interesting question is whether the strong negative bias in the estimation of the Hurst exponent observed for the discretization transformation is also observed for other types of (non-linear) transformation of the Gaussian process. Since one often obtains non-Gaussian long memory processes by transforming a fGN or a fARIMA process (Dittman and Granger (2002)), the question of the bias of the estimator of the Hurst exponent is of great interest. A second extension is to study the effect of round-off error on non-stationary processes. The discretization of a non-stationary process is, for example, a more realistic description of the effect of tick size on the price process, and therefore it will have more direct applications to the microstructure literature. The discretization of the price process induces round-off errors in the observed returns, and therefore also in the realized volatility. From a financial econometrics perspective, it would be interesting to consider also processes with stochastic volatility, i.e. processes where the increments of the process are uncorrelated, but the volatility is significantly correlated or is a long memory process. A very small scale example of this type of analysis has been performed in La Spada *et al.* (2011), where discretization of simulated price process with volatility described by an ARCH process has been considered, finding qualitative results similar to those presented in this paper. Finally, an interesting topic for further research is the extension of our results to continuous time process, and then the study of the combined effect of round-off error and discrete time sampling. We believe that these extensions are potentially of interest in the literature on realized volatility measures, such as the realized variance, that are imperfect estimates of actual volatility.

Since most natural and socio-economic time series are observed on a grid of values, i.e. the measured process is naturally discretized, we believe that our results are potentially of interest in many contexts. The severe bias of the long memory property of a discretized process should warn the scholars investigating processes on the underestimation of the Hurst exponent due to the non-linear transformation induced by round-off errors.

Acknowledgments

We are grateful to Yacine Aït-Sahalia, Fulvio Corsi, Gabriele Di Cerbo, Ulrich K. Müller, and Christopher Sims for their useful comments and discussions. We wish to thank J. D. Farmer for useful discussions inspiring the beginning of this work.

Appendix A. Distributional properties of the discretized process

In this appendix we consider the distributional properties of the discretized process of a generic weakly stationary Gaussian process. The probability mass function of the discretized process is

$$p_d(x) = \sum_{n=-\infty}^{\infty} q_n \delta(x - n\delta) \tag{A.1}$$

where

$$q_n = \int_{\delta(n-1/2)}^{\delta(n+1/2)} p(x)dx \tag{A.2}$$

and $\delta(x)$ is the Dirac delta function.

The m-th moment of the discretized process can therefore be written as

$$E[x_d^m] = \sum_{n=-\infty}^{\infty} q_n (n\delta)^m \tag{A.3}$$

Since x is Gaussian distributed, the variance D_d of the discretized process can be calculated explicitly. From the above expression with $m = 2$ we obtain

$$D_d = D \sum_{n=-\infty}^{\infty} \frac{n^2}{2\zeta} \left[erf\left(\frac{2n+1}{2\sqrt{2\zeta}} \right) - erf\left(\frac{2n-1}{2\sqrt{2\zeta}} \right) \right] \tag{A.4}$$

Left panel of Figure 1 shows the ratio D_d/D as a function of the scaling parameter ζ. It is worth noting that this ratio is not monotonic. For small ζ the ratio goes to zero because δ is very large and essentially all the probability mass falls in the bin centered at zero. In this regime the variance ratio goes to zero as

$$\frac{D_d}{D} \simeq 2\sqrt{\frac{2}{\pi}}\frac{e^{-1/8\zeta}}{\sqrt{\zeta}}. \tag{A.5}$$

When $\zeta \gg 1$ the ratio tends to one because the effect of discretization becomes irrelevant. In this regime $D_d/D \simeq 1 + 1/(12\zeta)$.

Analogously it is possible to calculate the kurtosis $\kappa_d = E[x_d^4]/(E[x_d^2])^2$ of the discretized process. It is direct to show that the kurtosis is

$$\kappa_d = \frac{\sum_{n=1}^{\infty} n^4 \left[erf\left(\frac{2n+1}{2\sqrt{2\zeta}}\right) - erf\left(\frac{2n-1}{2\sqrt{2\zeta}}\right)\right]}{\left(\sum_{n=1}^{\infty} n^2 \left[erf\left(\frac{2n+1}{2\sqrt{2\zeta}}\right) - erf\left(\frac{2n-1}{2\sqrt{2\zeta}}\right)\right]\right)^2} \tag{A.6}$$

For small ζ the kurtosis diverges as

$$\kappa_d \simeq \sqrt{\frac{\pi}{8\zeta}}e^{1/8\zeta} \tag{A.7}$$

because the fourth moment goes to zero slower than the squared second moment. For large ζ the kurtosis converges as expected to the Gaussian value 3 as $\kappa_d \simeq 3 - 1/(120\,\zeta^2)$. Note that the kurtosis reaches its asymptotic value 3 from below, since it reaches a minimum of roughly 2.982 at $\zeta \simeq 0.53$ and then converges to three from below.

Trivially, when the discretization is obtained by taking the sign function the variance of the discretized process is $D_d = 1$ and the kurtosis is $\kappa_d = 1$.

Appendix B. Proofs for Section 3

Proof of Proposition 1. The discretized process, $x_d(i)$, is a non-linear transformation of the underlying continuous process, $x(i)$. Let us denote the discretization transformation with $g(\cdot)$, so that $x_d = g(x)$. From (11) we know that

$$\gamma_d(k) = \sum_{j=1}^{\infty} g_j^2 \rho^j(k) \qquad \forall\ k = 0, 1, \ldots$$

where ρ is the autocorrelation function of the underlying continuous process, and g_j are defined in (12).

In order to compute the correlation properties of the discretized process we need to compute the coefficients g_j. Since the function $g(x)$ is an odd function $g_j = 0$ for j even, while all the odd coefficients are non-vanishing. Therefore the discretization function has Hermite rank 1 and can be written as an infinite sum of Hermite (odd) polynomials. The generic g_j coefficient is

$$g_j = \frac{1}{\sqrt{2\pi}} \sum_{n=-\infty}^{\infty} n\delta \int_{(n-1/2)\delta}^{(n+1/2)\delta} H_j(x)e^{-x^2/2}dx \to \sqrt{\frac{D}{2\pi}} \sum_{n=-\infty}^{\infty} \frac{n}{\sqrt{\zeta}} \int_{(n-1/2)/\sqrt{\zeta}}^{(n+1/2)/\sqrt{\zeta}} H_j(x)e^{-x^2/2}dx$$

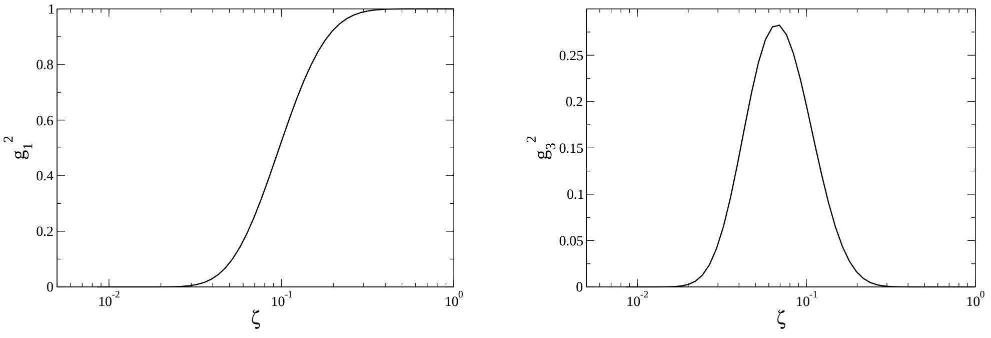

Figure B.8: Hermite coefficients g_1^2 (left) and g_3^2 (right) of the discretization function as a function of the discretization parameter ζ. The variance of the original process is normalized to 1.

The first Hermite polynomial is $H_1(x) = x$ and the coefficient g_1 is

$$\frac{g_1}{\sqrt{D}} = \sqrt{\frac{2}{\pi\zeta}} \sum_{k=0}^{\infty} \exp\left[-\frac{(2k+1)^2}{8\zeta}\right] = \frac{1}{\sqrt{2\pi\zeta}} \vartheta_2(0, e^{-1/2\zeta})$$

where $\vartheta_a(u, q)$ is the elliptic theta function. For large ζ, $g_1 \simeq \sqrt{D}$, while for small ζ the coefficient g_1 goes to zero as

$$g_1 \simeq \sqrt{D} \sqrt{\frac{2}{\pi}} \frac{e^{-1/8\zeta}}{\sqrt{\zeta}}$$

The second non-vanishing coefficient g_3 is given by

$$\frac{g_3}{\sqrt{D}} = -\sqrt{\frac{1}{3\pi\zeta}} \sum_{k=0}^{\infty} \exp\left[-\frac{(2k+1)^2}{8\zeta}\right] + \frac{1}{\sqrt{48\pi\zeta^3}} \sum_{k=0}^{\infty} (2k+1)^2 \exp\left[-\frac{(2k+1)^2}{8\zeta}\right]$$

The functional dependence of g_1^2 and g_3^2 on ζ is shown in Figure B.8.

In principle one could calculate all the coefficients g_j. Here we want to focus on the case when the correlation coefficient ρ is small, so that it suffices to consider the first two coefficients g_1 and g_3. The reason for this choice is that we are interested in the long memory properties of the discretized series which manifest themselves in the asymptotic behavior of the autocorrelation function, precisely where $\rho(k)$ is small.

Therefore, from (11) we have

$$\gamma_d(k) = \frac{g_1^2}{D} \gamma(k) \left(1 + O\left(\gamma(k)^2\right)\right) \qquad \text{for large } k\,. \tag{B.1}$$

If we plug (1) and our formula for g_1 into (B.1), we get the result. □

Proof of Proposition 2. From Proposition 1 we know that for large k

$$\gamma_d(k) \;=\; \left(\frac{\vartheta_2(0,e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 k^{-\alpha}\left(\sum_{i=0}^{\infty} b_i k^{-\beta_i}\right)\left[1+O\left(k^{-2\alpha}\left(\sum_{i=0}^{\infty} b_i k^{-\beta_i}\right)^2\right)\right]$$

Under the assumption that $L \in \mathcal{L}(\infty,\{b_i\},\{\beta_i\})$, we can write $\sum_{i=0}^{\infty} b_i k^{-\beta_i} = b_0\left(1+O\left(k^{-\beta_1}\right)\right)$ and apply Mertens' theorem to get

$$\left(\sum_{i=0}^{\infty} b_i k^{-\beta_i}\right)^2 \;=\; \sum_{i=0}^{\infty}\sum_{j=0}^{i} b_j b_{i-j} k^{-(\beta_j+\beta_{i-j})} = b_0^2 + O\left(k^{-\beta_1}\right) = O(1)$$

By substitution we get the result $\gamma_d(k) = \left(\frac{\vartheta_2(0,e^{-1/2\zeta})}{\sqrt{2\pi\zeta}}\right)^2 b_0\, k^{-\alpha}\left(1+O\left(k^{-\min(2\alpha,\beta_1)}\right)\right)$. □

Proof of Corollary 1. It follows directly from the definition of autocorrelation function and from Proposition 1. □

Proof of Proposition 3. As the discretization, the sign transformation is an odd function, and therefore $g_j = 0$ when j is even. When j is odd the coefficients of the sign function in Hermite polynomials are

$$g_j = 2\int_0^{\infty} H_j(x)\frac{e^{-x^2/2}}{\sqrt{2\pi}}dx = \frac{2^{j+1/2}\Gamma(j+1/2)}{\pi\sqrt{(2j+1)!}}.$$

By inserting these value in (11) we obtain the autocorrelation (and autocovariance) function of the sign of a Gaussian process

$$\gamma_s(k) = \rho_s(k) = \sum_{j=1}^{\infty} g_j^2 \rho(k)^j = \frac{2}{\pi}\arcsin\rho(k)$$

□

For the proof of Proposition 4 we need the following Lemma. Note that the proofs of the lemmas are at the end of this Appendix.

Lemma 1. *Under the assumptions of Proposition 4, let* $J_\alpha = \max\{j \in \mathbb{N}\cup\{0\} : (2j+1)\alpha \le 1\}$. *Then,*

$$\sum_{k=1}^{\infty}\sum_{j>J_\alpha}^{\infty} g_{2j+1}^2\left(k^{-\alpha}L(k)\right)^{2j+1}\cos(2\pi k\omega) = O(1) \qquad \textit{for all }\ \omega.$$

Proof of Proposition 4. For the sake of simplicity, in the following proof we consider the case of an underlying weakly stationary Gaussian process with unit variance, namely $D = 1$. In order to extend the proof to non unit variance we need simply to do the transformation $L(k) \to L(k)/D$. Obviously, $L(k)/D$ is still slowly varying at infinity.

From the Wiener-Khinchin theorem we know that

$$\phi_d(\omega) = (2\pi)^{-1} \sum_{k=-\infty}^{\infty} \gamma_d(k) \exp^{2\pi i k\omega} = \frac{\gamma_d(0)}{2\pi} + \frac{2}{2\pi} \sum_{k=1}^{\infty} \sum_{j=0}^{\infty} g_{2j+1}^2 [\gamma(k)]^{2j+1} \cos(2\pi k\omega)$$

Let $J_\alpha = \max\{j \in \mathbb{N} \cup \{0\} : (2j+1)\alpha \leq 1\}$. Obviously, $\forall\, \alpha \in (0,1)\ \exists\, J_\alpha < +\infty$. We can write

$$\begin{aligned} \phi_d(\omega) = \quad & \frac{\gamma_d(0)}{2\pi} + \frac{2}{2\pi} \sum_{k=1}^{\infty} \sum_{j=0}^{J_\alpha} g_{2j+1}^2 \left(k^{-\alpha} L(k)\right)^{2j+1} \cos(2\pi k\omega) \\ & + \frac{2}{2\pi} \sum_{k=1}^{\infty} \sum_{j>J_\alpha}^{\infty} g_{2j+1}^2 \left(k^{-\alpha} L(k)\right)^{2j+1} \cos(2\pi k\omega) \end{aligned} \tag{B.2}$$

The first term in the right hand side of (B.2) is trivially $O(1)$. From Lemma 1 the last term in the right-hand side of (B.2) is also $O(1)$. As we show below, the second term diverges as ω goes to zero.

From Zygmund (1959) (Theorem 2.6 and Theorem 2.15, Chapter V.2) we know that for $0 < \alpha < 1$, and for any slowly varying function $L(k)$,

$$\sum_{k=1}^{\infty} k^{-\alpha} L(k) \cos(2\pi k\omega) = \Gamma(1-\alpha) \sin\left(\frac{\alpha\pi}{2}\right) |\omega|^{\alpha-1} L(\omega^{-1}) + o\left(|\omega|^{\alpha-1} L(\omega^{-1})\right) \tag{B.3}$$

$$\sum_{k=1}^{\infty} k^{-1} L(k) \cos(2\pi k\omega) \sim \begin{cases} \int_1^{1/\omega} t^{-1} L(t) \mathrm{d}t & \text{if } \sum_{k=1}^{\infty} k^{-1} L(k) = \infty \\ \text{converges} & \text{if } \sum_{k=1}^{\infty} k^{-1} L(k) < \infty \end{cases} \tag{B.4}$$

as ω goes to zero. Note that we use the notation $f(x) \sim g(x)$ for $x \to x_0$, if $f(x)/g(x) \to 1$ as $x \to x_0$.

From Bojanic and Seneta (1973) and Seneta (1976) we know that every power of a slowly varying function is still a slowly varying function. Therefore (B.3) holds for the first J_α terms in the asymptotic expansion of the autocovariance of the discretized process. If $(2J_\alpha + 1)\alpha < 1$, then (B.3) holds also for the $(J_\alpha + 1)$-th term. If $(2J_\alpha + 1)\alpha = 1$, then (B.4) holds. However, as ω goes to zero (B.4) is always dominated by (B.3). Then, we can write (B.2) in the following way

$$\phi_d(\omega) = g_1^2 \pi^{-1} \Gamma(1-\alpha) \sin(\alpha\pi/2) |\omega|^{\alpha-1} L(|\omega|^{-1}) + o\left(|\omega|^{\alpha-1} L(|\omega|^{-1})\right) \tag{B.5}$$

By plugging our formula for g_1 into (B.5) we get the result. □

Proof of Proposition 5. For the sake of simplicity, in the following proof we consider the case of an underlying weakly stationary Gaussian process with unit variance, namely $D = 1$. In order to extend the proof to non unit variance we need simply to do the transformation $L(k) \to L(k)/D$. Obviously, $L(k)/D$ is still slowly varying at infinity. Moreover, we consider only the case $I = \infty$. The case $I < \infty$ is trivial.

From the Wiener-Khinchin theorem we know that

$$\phi_d(\omega) = (2\pi)^{-1} \sum_{k=-\infty}^{\infty} \gamma_d(k) \exp^{2\pi i k\omega} = \frac{\gamma_d(0)}{2\pi} + \frac{2}{2\pi} \sum_{k=1}^{\infty} \gamma_d(k) \cos(2\pi k\omega)$$

If $L \in \mathcal{L}(\infty, \{b_i\}, \{\beta_i\})$, then $L(k) = \sum_{i=0}^{\infty} b_i k^{-\beta_i}$ and converges absolutely for large k. Let $K > 0$ s.t. $\sum_{i=0}^{\infty} |b_i| k^{-\beta_i} < \infty$ and $0 < K^{-\alpha} \sum_{i=0}^{\infty} |b_i| k^{-\beta_i} < 1$ for all $k \geq K$.

We split the Fourier transform in the following way

$$\phi_d(\omega) \quad = \quad \frac{\gamma_d(0)}{2\pi} + \frac{2}{2\pi} \sum_{k=1}^{K} \gamma_d(k) \cos(2\pi k\omega) + \frac{2}{2\pi} \sum_{k>K} \left[\sum_{j=0}^{\infty} g_{2j+1}^2 \left(k^{-\alpha} \sum_{i=0}^{\infty} b_i k^{-\beta_i} \right)^{2j+1} \right] \cos(2\pi k\omega)$$

The first two terms are trivially $O(1)$. The third term diverges as ω goes to zero.

Because $\sum_i b_i k^{-\beta_i}$ converges absolutely for all $k \geq K$, by Mertens' theorem we can write

$$\left(\sum_{i=0}^{\infty} b_i k^{-\beta_i} \right)^{2j+1} = \sum_{i=0}^{\infty} \widetilde{b}_{j,i} k^{-\widetilde{\beta}_{j,i}} \qquad \forall\ j = 0, 1, 2, \ldots \quad (k \geq K) \tag{B.6}$$

where the series on the right hand side of (B.6) is the Cauchy product. Note that $\widetilde{b}_{0,i} = b_i$ and $\widetilde{\beta}_{0,i} = \beta_i$ for all i, while $\widetilde{b}_{j,0} = b_0^{2j+1}$ and $\widetilde{\beta}_{j,0} = 0$ for all j. By absolute convergence of the original series the Cauchy product on the right hand side of (B.6) also converges absolutely for all $k \geq K$. So, we can write

$$\sum_{k>K} \left[\sum_{j=0}^{\infty} g_{2j+1}^2 \left(k^{-\alpha} \sum_{i=0}^{\infty} b_i k^{-\beta_i} \right)^{2j+1} \right] \cos(2\pi k\omega) = \sum_{k>K} \left[\sum_{j=0}^{\infty} \sum_{i=0}^{\infty} g_{2j+1}^2 \widetilde{b}_{j,i} k^{-((2j+1)\alpha + \widetilde{\beta}_{j,i})} \right] \cos(2\pi k\omega) \tag{B.7}$$

Under our assumption, from Zygmund (1959) (Chapter I, Theorem 2.6) and Theorem 8.3 in Rudin (1976) for $\omega > 0$ we can exchange the series in (B.7) in the following way

$$\sum_{k>K} \left[\sum_{j=0}^{\infty} g_{2j+1}^2 \left(k^{-\alpha} \sum_{i=0}^{\infty} b_i k^{-\beta_i} \right)^{2j+1} \right] \cos(2\pi k\omega) = \sum_{j=0}^{\infty} g_{2j+1}^2 \sum_{i=0}^{\infty} \widetilde{b}_{j,i} \sum_{k>K} k^{-((2j+1)\alpha + \widetilde{\beta}_{j,i})} \cos(2\pi k\omega) \tag{B.8}$$

Let $J_\alpha \equiv \max\{j \in \mathbb{N} \cup \{0\} : (2j+1)\alpha \leq 1\}$ and $\widetilde{I}(j) \equiv \{i \in \mathbb{N} \cup \{0\} : (2j+1)\alpha + \widetilde{\beta}_{j,i} \leq 1\}$. Obviously $J_\alpha < \infty$, $\widetilde{I}(j) = \emptyset$ for $j > J_\alpha$, and under our assumptions $\#\widetilde{I}(j) < \infty$ for all j[6].

Under our assumptions the series in (B.8) converges absolutely for all $\omega > 0$, by the Dini-Riemann theorem we can split and rearrange the series in the following way

$$\begin{aligned}
&\sum_{k>K} \sum_{j=0}^{\infty} g_{2j+1}^2 k^{-(2j+1)\alpha} \left(\sum_{i=0}^{\infty} b_i k^{-\beta_i} \right)^{2j+1} \cos(2\pi k\omega) = \\
&\sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i \in \widetilde{I}(j)} \widetilde{b}_{j,i} \sum_{k>K}^{\infty} k^{-\eta_{j,i}} \cos(2\pi k\omega) + \sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i \notin \widetilde{I}(j)} \widetilde{b}_{j,i} \sum_{k>K}^{\infty} k^{-\eta_{j,i}} \cos(2\pi k\omega) + \\
&+ \sum_{j=J_\alpha+1}^{\infty} g_{2j+1}^2 \sum_{i=0}^{\infty} \widetilde{b}_{j,i} \sum_{k>K}^{\infty} k^{-\eta_{j,i}} \cos(2\pi k\omega),
\end{aligned} \tag{B.9}$$

where $\eta_{j,i} \equiv (2j+1)\alpha + \widetilde{\beta}_{j,i}$.

---

[6] The symbol $\#A$ denotes the cardinality of the set A.

Lemma 2. *The last two terms in (B.9) are $O(1)$.*

Now we focus on the first term in (B.9). First, notice that $\eta_{j,i} \leq 1$ for $\{0 \leq j \leq J_\alpha, i \in \widetilde{I}(j)\}$. From Zygmund (1959) (Chapter II.13 and Chapter V, Theorem 2.15) we know that for $\omega \to 0^+$ and $0 < \beta < 1$

$$\sum_{k=1}^{\infty} k^{-\beta} \cos(2\pi k\omega) = \Gamma(1-\beta)\sin(\beta\pi/2)|\omega|^{\beta-1} + O(1), \tag{B.10}$$

$$\sum_{k=1}^{\infty} k^{-1} \cos(2\pi k\omega) \sim \ln|\omega|^{-1}. \tag{B.11}$$

Second, in (B.9) we have $\sum_{j=0}^{J_\alpha} \#\widetilde{I}(j) < \infty$ terms of this kind, with the only difference that the sum over k starts from $k = K+1$ instead of $k = 1$. Then, we can write

$$\sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i\in\widetilde{I}(j)} \widetilde{b}_{j,i} \sum_{k>K} k^{-\eta_{j,i}} \cos(2\pi k\omega) = \sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i\in\widetilde{I}(j)} \widetilde{b}_{j,i} \sum_{k=1}^{\infty} k^{-\eta_{j,i}} \cos(2\pi k\omega) + O(1)$$

Now, for sake of simplicity we assume $\eta_{j,i} < 1$ for all $0 \leq j \leq J_\alpha$ and $i \in \widetilde{I}(j)$. This simplification is not crucial. In fact, if there exist (j', i') s.t. $\eta_{j',i'} = 1$, then, according to formulas (B.10) and (B.11), the Fourier transform of these terms will be dominated by the Fourier transform of the other terms corresponding to $\eta_{j,i} < 1$ as $\omega \to 0^+$. From (B.10) we can write

$$\sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i\in\widetilde{I}(j)} \widetilde{b}_{j,i} \sum_{k>K}^{\infty} k^{-\eta_{j,i}} \cos(2\pi k\omega) = \sum_{j=0}^{J_\alpha} \sum_{i\in\widetilde{I}(j)} g_{2j+1}^2 \widetilde{b}_{j,i} c_\phi^{j,i} |\omega|^{\eta_{j,i}-1} + O(1) \tag{B.12}$$

where $c_\phi^{j,i}$ are the coefficients given by (B.10) and depend on $\eta_{j,i} = (2j+1)\alpha + \widetilde{\beta}_{j,i}$.

The leading term in (B.12) is trivially $O\left(\omega^{\alpha-1}\right)$, i.e. when $j = 0$ and $i = 0$. If $\widetilde{I}(0) = \{0\}$ (i.e. $\alpha + \beta_1 > 1$) and $J_\alpha = 0$ (i.e. $3\alpha > 1$), then the sub-leading term is trivially $O(1)$. On the other hand, if $\#\widetilde{I}(0) \geq 2$ (i.e. $\alpha + \beta_1 < 1$) or $J_\alpha \geq 1$ (i.e. $3\alpha < 1$), the sub-leading term is either $O\left(\omega^{\alpha+\beta_1-1}\right)$ corresponding to $j = 0$ and $i = 1$, or $O\left(\omega^{3\alpha-1}\right)$ corresponding to $j = 1$ and $i = 0$. All the other terms are either $O(1)$ or diverge more slowly as ω goes to zero, because the coefficients β_i are strictly increasing in i. So, the overall sub-leading term will be $O\left(|\omega|^{\min(\alpha+\beta_1-1, 3\alpha-1, 0)}\right)$. Then, by collecting together all the terms $O(1)$, for small ω we get

$$\phi_d(\omega) \;=\; g_1^2\pi^{-1}\Gamma(1-\alpha)\sin(\alpha\pi/2)b_0|\omega|^{\alpha-1}\left(1 + O\left(|\omega|^{\min(\beta_1, 2\alpha, 1-\alpha)}\right)\right)$$

If we want to take into account the case in which some of the exponents $\eta_{j,i}$ lie on the unit circle,we just need to use (B.11) instead of (B.10). If $\alpha + \beta_1 = 1$, by using (B.11) we get

$$\phi_d(\omega) = g_1^2\pi^{-1}\Gamma(1-\alpha)\sin(\alpha\pi/2)b_0|\omega|^{\alpha-1}\left(1 + O\left(|\omega|^{1-\alpha}\ln|\omega|^{-1}\right) + O\left(|\omega|^{2\alpha}\right)\right)$$

Similarly, if $3\alpha = 1$, by using (B.11) we get

$$\phi_d(\omega) = g_1^2\pi^{-1}\Gamma(1-\alpha)\sin(\alpha\pi/2)b_0|\omega|^{\alpha-1}\left(1 + O\left(|\omega|^{1-\alpha}\ln|\omega|^{-1}\right) + O\left(|\omega|^{\beta_1}\right)\right)$$

If $\alpha + \beta_1 = 3\alpha = 1$, then the error term will simply be $O\left(|\omega|^{1-\alpha}\ln|\omega|^{-1}\right)$.

If we substitute our expression for g_1 we get the result. □

Proof of Corollary 2. If L is analytic at infinity, then $L(k) = \sum_{n=0}^{\infty} b_n k^{-n}$ for large k for some $\{b_n\}$, and the series converges absolutely inside its radius of convergence. Then, $L \in \mathcal{L}(\infty, \{b_i\}, \{\beta_i\})$ and satisfies the assumptions of Proposition 5. According to our notation $\beta_1 \geq 1$. By applying Proposition 5 and our formula for g_1^2 we get the result. □

Proof of Proposition 6. The proof is similar to the proof of Proposition 4, and thus omitted. □

Proof of Proposition 7. The proof is similar to the proof of Proposition 5, and thus omitted. □

Proof of Corollary 3. The proof is similar to the proof of Corollary 2, and thus omitted. □

Proofs of lemmas for Section 3

Proof of Lemma 1. Obviously, $\forall\, \alpha \in (0,1)\ \exists\, J_\alpha < +\infty$. Let $\delta > 0$ such that $(2J_\alpha + 3)(\alpha - \delta) > 1$. From Bojanic and Seneta (1973) we know that $k^{-\varepsilon}L(k) \to 0$ as $k \to \infty$, for all $\varepsilon > 0$. Then, $\exists\, K > 1$ s.t. $k^{-\delta}L(k) < 1\ \ \forall\, k \geq K$. So we can write,

$$\left| \sum_{k=1}^{\infty} \sum_{j>J_\alpha}^{\infty} g_{2j+1}^2 \left(k^{-\alpha} L(k)\right)^{2j+1} \cos(2\pi k \omega) \right| \leq \sum_{k=1}^{K-1} \sum_{j=0}^{\infty} g_{2j+1}^2 \left(k^{-\alpha} L(k)\right)^{2j+1} + \sum_{k=K}^{\infty} \sum_{j>J_\alpha}^{\infty} g_{2j+1}^2 \left(k^{-\alpha+\delta}\right)^{2j+1} \tag{B.13}$$

The first term in (B.13) is the finite sum of $K-1$ terms of the autocovariance of the discretized process, and therefore it is trivially $O(1)$.

The second term in (B.13) can be bounded by a geometric series from above. In fact, from $\sum_{j=0}^{\infty} g_{2j+1}^2 < \infty$ we know that g_j are bounded and go to zero as j goes to ∞. Let $\overline{g} = \max_{j \in \mathbb{N}} g_{2j+1}$ and $\alpha_0 = (2J_\alpha + 3)(\alpha - \delta) > 1$. Then, we can write

$$\sum_{j>J_\alpha}^{\infty} g_{2j+1}^2 \left(k^{-\alpha+\delta}\right)^{2j+1} \leq \overline{g} \sum_{j>J_\alpha}^{\infty} \left(k^{-\alpha_0}\right)^{\lfloor \frac{(2j+1)(\alpha-\delta)}{\alpha_0} \rfloor}$$

where $\lfloor x \rfloor$ is the largest integer not greater than x. Note that for any integer $m \geq 1$ there can be at most $J_\alpha + 2$ (consecutive) terms s.t. $m \leq \frac{(2j+1)(\alpha-\delta)}{\alpha_0} < m+1$. Then, we can write

$$\sum_{k=K}^{\infty} \sum_{j>J_\alpha}^{\infty} g_{2j+1}^2 \left(k^{-\alpha+\delta}\right)^{2j+1} \ \ \leq\ \ \overline{g}(J_\alpha + 2) \sum_{k=K}^{\infty} \sum_{j=1}^{\infty} \left(k^{-\alpha_0}\right)^j \leq \frac{\overline{g}(J_\alpha + 2)}{1 - K^{-\alpha_0}} \sum_{k=K}^{\infty} k^{-\alpha_0} < \infty$$

where the last inequality holds because $\alpha_0 > 1$. Then, we conclude that the second term in (B.13) is $O(1)$, and therefore we have the result. □

Proof of Lemma 2. First, notice that $\eta_{j,i} > 1$ for $\{0 \leq j \leq J_\alpha, i \notin \widetilde{I}(j)\}$ and $\{j > J_\alpha, i \in \mathbb{N} \cup 0\}$.

Second, note that for $\eta > 1$

$$\left| \sum_{k>K} k^{-\eta} \cos(2\pi k \omega) \right| \leq \sum_{k>K} k^{-\eta} < \int_K^{\infty} u^{-\eta}\, \mathrm{d}u = \frac{K^{-\eta+1}}{\eta - 1}.$$

Let $\eta_1 \equiv \min\limits_{\substack{0\le j\le J_\alpha \\ i\notin\widetilde{I}(j)}} \eta_{j,i}$ and $\eta_2 \equiv \min\limits_{\substack{j>J_\alpha \\ i=0,1,\ldots}} \eta_{j,i}$. Then, we can write

$$\begin{aligned}
\left|\sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i\notin\widetilde{I}(j)} \widetilde{b}_{j,i} \sum_{k>K} k^{-\eta_{j,i}} \cos(2\pi k\omega)\right| &< \sum_{j=0}^{J_\alpha} g_{2j+1}^2 \sum_{i\notin\widetilde{I}(j)} \widetilde{b}_{j,i} \frac{K^{-\eta_{j,i}+1}}{\eta_{j,i}-1} < \frac{K}{\eta_1 - 1} \\
\left|\sum_{j>J_\alpha} g_{2j+1}^2 \sum_{i=0}^{\infty} \widetilde{b}_{j,i} \sum_{k>K} k^{-\eta_{j,i}} \cos(2\pi k\omega)\right| &< \sum_{j>J_\alpha} g_{2j+1}^2 \sum_{i=0}^{\infty} \widetilde{b}_{j,i} \frac{K^{-\eta_{j,i}+1}}{\eta_{j,i}-1} < \frac{K}{\eta_2 - 1}
\end{aligned}$$

where we used $\eta_1, \eta_2 > 1$, $0 < K^{-\alpha} \sum_i |b_i| K^{-\beta_i} < 1$ and $\sum_{j=0}^{\infty} g_{2j+1}^2 = 1$. □

Appendix C. Proofs for Section 4

For the proofs of Proposition 8 and Theorem 1 we need the following lemma. Note that the proofs of the lemmas are at the end of this Appendix.

Lemma 3. *Let* $m \in \mathbb{N}$, $\alpha < 1$, *and*

$$R(\alpha) = -\alpha(\alpha-1)\int_1^m \frac{B_2(\{1-t\})}{2!} t^{\alpha-2}\mathrm{d}t \tag{C.1}$$

$$\widetilde{R}(\alpha) = -\int_1^m \frac{B_2(\{1-t\})}{2!} t^{-2+\alpha}\left(\alpha(\alpha-1)\log t - 1 + 2\alpha\right)\mathrm{d}t \tag{C.2}$$

where $B_2(x) = 1/6 - x + x^2$ *is the third Bernoulli polynomial and* $\{x\}$ *represents the fractional part of the real number* x*. Then,* $R(\alpha)$ *and* $\widetilde{R}(\alpha)$ *converge as* $m \to \infty$.

Note that $R(\alpha)$ and $\widetilde{R}(\alpha)$ are the remainders of a first order Euler-Maclaurin expansion of the sums $\sum_{k=1}^{i} k^\alpha$ and $\sum_{k=1}^{i} k^\alpha \log k$, respectively.

Proof of Proposition 8. From the proof of Proposition 5 we know that $\phi^*(\omega_j) = 1 + C\omega_j^{\underline{\alpha}} + O\left(\omega_j^{\underline{\alpha}+\varepsilon}\right)$ for some $\varepsilon > 0$. So, we can write

$$-\frac{1}{2S_{xx}}\sum_{j=1}^{m} a_j \log\phi_d^*(\omega_j) = -\frac{1}{2S_{xx}}\sum_{j=1}^{m} a_j\left(C\omega_j^{\underline{\alpha}} + O\left(\omega_j^{\min(\underline{\alpha}+\varepsilon, 2\underline{\alpha})}\right)\right)$$

From Hurvich and Beltrao (1993),

$$a_j = \log j - \frac{1}{m}\sum_{k=1}^{m}\log k + O\left(\frac{m^2}{N^2}\right) \tag{C.3}$$

where the remainder term is uniform in j.

Using the Euler-Maclaurin formula we can write

$$\begin{aligned}
&\sum_{j=1}^{m} j^{\underline{\alpha}} \log j = \frac{m^{\underline{\alpha}+1}\log m}{\underline{\alpha}+1} - \frac{m^{\underline{\alpha}+1}}{(1+\underline{\alpha})^2} + \frac{1}{2}m^{\underline{\alpha}}\log m + \frac{B_2\underline{\alpha}}{2}m^{\underline{\alpha}-1}\log m + O(1)\\
&\sum_{j=1}^{m} j^{\underline{\alpha}} = \frac{m^{\underline{\alpha}+1}}{\underline{\alpha}+1} + \frac{1}{2}m^{\underline{\alpha}} + \frac{B_2\underline{\alpha}}{2}m^{\underline{\alpha}-1} + O(1)\\
&\frac{1}{m}\sum_{k=1}^{m}\log k = \log m - 1 + o(1)
\end{aligned}$$

where we used Lemma 3 to establish that the remainders of the Euler-Maclaurin formula are $O(1)$. Using these formulas together with (C.3) it follows that $\sum_{j=1}^{m} a_j\omega_j^{\underline{\alpha}} = \frac{(2\pi)^{\underline{\alpha}}}{N^{\underline{\alpha}}}\left(\frac{\underline{\alpha}}{(1+\underline{\alpha})^2}m^{\underline{\alpha}+1} + o\left(m^{\underline{\alpha}+1}\right)\right)$ and $\sum_{j=1}^{m} a_j O\left(\omega_j^{\min(\underline{\alpha}+\varepsilon,2\underline{\alpha})}\right) = O\left(\left(\frac{m}{N}\right)^{\alpha_1} m\log m\right)$, where $\alpha_1 = \underline{\alpha} + \min(\underline{\alpha},\varepsilon)$.

Since $S_{xx} = m\,(1+o(1))$ and since $m^{\alpha_1}N^{-\alpha_1}\log m = o(m^{\underline{\alpha}}/N^{\underline{\alpha}})$ by assumption, we conclude that

$$-\frac{1}{2S_{xx}}\sum_{j=1}^{m} a_j \log\phi_d^*(\omega_j) = -\frac{\underline{\alpha}C(2\pi)^{\underline{\alpha}}}{2(1+\underline{\alpha})^2}\left(\frac{m}{N}\right)^{\underline{\alpha}} + o\left(m^{\underline{\alpha}}/N^{\underline{\alpha}}\right)$$

☐

For the proof of Theorem 1 we need the following lemmas.

Lemma 4. *Let $i, k \in \mathbb{N}$, $\alpha > 0$, and $\alpha \neq 1, 2$. Then, as $i \to \infty$*

$$\sum_{k=1}^{i}(i-k)k^{-\alpha} = A_0(\alpha)i^{2-\alpha} + A_1(\alpha)\,i + O(1)$$

where $A_0(z) = \frac{1}{(1-z)(2-z)}$ and $A_1(z) = -\frac{(z+2)(z+3)}{12(1-z)} + R(z)$ and $R(\cdot)$ is defined as in (C.1).

Lemma 5. *Let $i, k \in \mathbb{N}$. Then, as $i \to \infty$*

$$\begin{aligned}
\sum_{k=1}^{i}(i-k)k^{-1} &= i\ln i + \left(-\frac{5}{12} + R_1\right)i + O(1)\\
\sum_{k=1}^{i}(i-k)k^{-2} &= \left(\frac{5}{3} + R_2\right)i - \ln i + O(1)
\end{aligned}$$

where $R_1 \equiv R(\alpha = 1)$ and $R_2 \equiv R(\alpha = 2)$.

Before proving Theorem 1 we prove the following proposition.

Proposition 9. *Under the assumptions of Theorem 1, let us define $\Sigma_m = Cov(y(i), y(j))$, i.e. the covariance matrix of the integrated process $(y(1), \ldots, y(m))$. Then,* *(i) if* $\beta \neq 2H-1$, *then*

$$\Sigma_m = \frac{A}{2H(2H-1)} \quad \Big(i^{2H}\left(1+O(i^{-\min(2H-1,\beta)})\right) + j^{2H}\left(1+O(j^{-\min(2H-1,\beta)})\right) + \\ - |i-j|^{2H}\left(1+O(|i-j|^{-\min(2H-1,\beta)})\right)\Big]$$

(ii) if $\beta = 2H-1$, *then*

$$\Sigma_m = \frac{A}{2H(2H-1)} \quad \Big[i^{2H}\left(1+O(i^{1-2H}\ln i)\right) + j^{2H}\left(1+O(j^{1-2H}\ln j)\right) + \\ - |i-j|^{2H}\left(1+O(|i-j|^{1-2H}\ln|i-j|)\right)\Big]$$

Proof. Under the assumptions on $x(k)$, for $1 \leq i, j, \leq m$ we can write

$$\begin{aligned} \Sigma_m &= Cov(y(i), y(j)) = \sum_{k=1}^{i}\sum_{l=1}^{j} Cov(x(k), x(l)) = \sum_{k=1}^{i}(i-k)\,\gamma(k) + \\ &+ \sum_{k=1}^{j}(j-k)\,\gamma(k) - \sum_{k=1}^{|i-j|}(|i-j|-k)\,\gamma(k) + \min(i,j)\,\gamma(0) \end{aligned} \tag{C.4}$$

where $\gamma(0)$ is the variance of the process $x(t)$. By substituting the explicit functional form for $\gamma(k)$ and by the definition of $O(\cdot)$ we get

$$\sum_{k=1}^{i}(i-k)\,\gamma(k) \leq A\sum_{k=1}^{i}(i-k)\,k^{2H-2} + M\sum_{k=1}^{i}(i-k)k^{2H-2-\beta}$$

for some $M > 0$ sufficiently large. By Lemma 4 we have $A\sum_{k=1}^{i}(i-k)\,k^{2H-2} = A\left(\frac{i^{2H}}{2H(2H-1)} + O(i)\right)$.
Now, we consider the following cases:

(i) $\beta \neq 2H-1$. In this case we have to distinguish two cases.

If $\beta \neq 2H$, we can use Lemma 4 and obtain

$$\sum_{k=1}^{i}(i-k)\,k^{2H-2-\beta} = A_0(2H-2-\beta)\,i^{2H-\beta} + A_1(2H-2-\beta)\,i + O(1) = i^{2H}\,O\left(i^{-\min(2H-1,\beta)}\right)$$

If $\beta = 2H$, then we can use Lemma 5

$$\sum_{k=1}^{i}(i-k)\,k^{2H-2-\beta} = \left(\frac{5}{3} + R_2\right)i - \ln i + O(1) = O\,(i)$$

Then, we repeat the same calculation for the second and third term in (C.4). By noting that $\min(i,j)$ is either of order $O(i)$ or $O(j)$ and putting together all the terms, we obtain the result.

(ii) $\beta = 2H - 1$. In this case we can use Lemma 5

$$\sum_{k=1}^{i}(i-k)\,k^{2H-2-\beta} = \left(i\ln i + \left(-\frac{5}{12} + R_1\right) i + O(1)\right) = i^{2H} O\left(i^{1-2H}\ln i\right)$$

Then, we repeat the same calculation for the second and third term in (C.4). By noting that $\min(i, j)$ is either of order $O(i)$ or $O(j)$ and putting together all the terms, we obtain the result.

□

Proof of Theorem 1. Following Bardet and Kammoun (2008),

$$F_1^2(m) = \frac{1}{m}(y^{(1)} - P_{E_1}y^{(1)})'(y^{(1)} - P_{E_1}y^{(1)}) = \frac{1}{m}(y^{(1)\prime}y^{(1)} - y^{(1)\prime}P_{E_1}y^{(1)}),$$

where E_1 is the vector subspace of $\mathbb{R}^m$ generated by the two vectors $e_1 = (1, \ldots, 1)'$ and $e_2 = (1, 2, \ldots, m)$, P_{E_1} is the matrix of the orthogonal projection on E_1, and the second equality holds because the projection operator is idempotent. As a consequence,

$$\mathbb{E}\left[F_1^2(m)\right] = \frac{1}{m}\left(\mathrm{Tr}(\Sigma_m) - \mathrm{Tr}(P_{E_1}\Sigma_m)\right)$$

(i) If $\beta \neq 2H - 1$, from Proposition 9 we get

$$\mathrm{Tr}(\Sigma_m) \;=\; \frac{A}{H(2H-1)} m^{2H+1}\left(\int_0^1 x^{2H}\mathrm{d}x + O(m^{-\min(2H-1,\beta)}) + O(m^{-1})\right)$$

Note that the error of order $O(m^{-1})$ comes from approximating the sum with the integral. Therefore, we obtain

$$\mathrm{Tr}(\Sigma_m) = \frac{Am^{2H+1}}{H(2H-1)}\frac{1}{2H+1}\left(1 + O(m^{-\min(2H-1,\beta)})\right) \tag{C.5}$$

For the term $\mathrm{Tr}(P_{E_1}\Sigma_n)$, we use the following representation of the projection operator

$$P_{E_1} = \frac{2}{n(n-1)}\left((2n+1) - 3(i+j) + 6\frac{i\cdot j}{1+n}\right) \tag{C.6}$$

Then, using (C.6) and Proposition 9, we can write

$$\begin{aligned}
\mathrm{Tr}(P_{E_1}\Sigma_n) = \quad & \frac{2Am^{2H+1}m^2}{m(m-1)2H(2H-1)}\left[\sum_{i=1}^{m}\sum_{j=1}^{m}\frac{1}{m^2}\left(\left(2+\frac{1}{m}\right) - 3\frac{i+j}{m} + 6\frac{ij}{m(m+1)}\right)\cdot\right.\\
& \left(\left(\frac{i}{m}\right)^{2H}\left(1 + O(i^{-\min(2H-1,\beta)})\right) + \left(\frac{j}{m}\right)^{2H}\left(1 + O(j^{-\min(2H-1,\beta)})\right) + \right.\\
& \left.\left. -\left(\frac{|i-j|}{m}\right)^{2H}\left(1 + O(|i-j|^{-\min(2H-1,\beta)})\right)\right)\right]
\end{aligned}$$

Approximating sums with integrals we get

$$\begin{aligned}
\mathrm{Tr}(P_{E_1}\Sigma_m) &= \frac{Am^{2H+1}}{H(2H-1)}\left(1+O(m^{-\min(2H-1,\beta)})+O(m^{-1})\right)\cdot \\
&\quad \cdot\int_0^1\int_0^1\left[(2-3(x+y)+6xy)\left(x^{2H}+y^{2H}-|x-y|^{2H}\right)\right]\mathrm{d}x\mathrm{d}y \\
&= \frac{Am^{2H+1}}{H(2H-1)}\frac{1+H(4+H)}{(1+H)(2+H)(1+2H)}\left(1+O(m^{-\min(2H-1,\beta)})\right) \qquad \text{(C.7)}
\end{aligned}$$

Putting together (C.5) and (C.7) we obtain

$$\frac{1}{m}\left(\mathrm{Tr}(\Sigma_m)-\mathrm{Tr}(P_{E_1}\Sigma_m)\right)=\frac{A}{H(2H-1)}f(H)m^{2H}\left(1+O(m^{-\min(2H-1,\beta)})\right)$$

which is the formula of $\mathbb{E}\left[F_1^2(m)\right]$.

(ii) If $\beta = 2H-1$, the proof is exactly the same, except for replacing all the terms like $O(i^{-\min(2H-1,\beta)})$ with the terms $O(i^{1-2H}\ln i)$.

□

Proof of Corollary 4. It follows from the autocovariance of a fractional Gaussian noise (see formula (3)). The proof is very similar to the proof of Theorem 1, and thus omitted. However, a complete proof can be found in Bardet and Kammoun (2008) (see Proof of Property 3.1. therein). □

Proof of Corollary 5. It follows from Proposition 2 and Theorem 1. □

Proof of Corollary 6. It follows from Proposition 3 and Theorem 1. □

Proofs of lemmas for Section 4

Proof of Lemma 3. First we prove that $R(\alpha)$ converges. Because $|B_2(\{1-t\})| \le B_2(0) = 1/6$ for all t, we have $|R(\alpha)| \le \frac{|\alpha(\alpha-1)|}{12}\int_1^m t^{-2+\alpha}\mathrm{d}t$, where the integral on the right-hand side converges as $m \to \infty$ because $2-\alpha > 1$.

Now we prove that $\widetilde{R}(\alpha)$ converges. Pick $\varepsilon > 0$ s.t. $2-\alpha-\varepsilon > 1$. One can always find such ε because $\alpha < 1$ by assumption. Because $\log t$ is slowly varying, there exists $T > 1$ s.t. $t^{-2+\alpha}\log t < t^{-2+\alpha+\varepsilon}$ for all $t > T$. Because $|B_2(\{1-t\})| \le 1/6$ for all $t \ge 1$, we can write

$$|\widetilde{R}(\alpha)| < \frac{1}{12}\int_1^T t^{-2+\alpha}\left(\alpha(\alpha-1)\log t-1+2\alpha\right)\mathrm{d}t+\frac{\alpha(\alpha+1)}{12}\int_T^m t^{-2+\alpha+\varepsilon}\mathrm{d}t$$

where the second integral converges as $m \to \infty$ because $2-\alpha-\varepsilon > 1$. □

Proof of Lemma 4. By using Euler-Maclaurin formula up to the first order we obtain

$$i\sum_{k=1}^{i}k^{-\alpha} = i\left(\frac{i^{1-\alpha}-1}{1-\alpha}+\frac{i^{-\alpha}+1}{2}+\frac{B_2}{2!}(-\alpha)(i^{-\alpha-1}-1)+R(\alpha)\right)$$

where $B_2 = 1/6$ is the third Bernoulli number, and $R(\alpha)$ is the remainder of the Euler-Maclaurin expansion given by (C.1). From Lemma 3 we know that $R(\alpha)$ converges, as $i \to \infty$. So, we can write

$$i \sum_{k=1}^{i} k^{-\alpha} = \frac{i^{2-\alpha}}{1-\alpha} + A_1(\alpha) i + \frac{i^{1-\alpha}}{2} - \frac{\alpha\, i^{-\alpha}}{12}$$

where $A_1(\cdot)$ is defined as in Lemma 4. Note that the second-order term is $O(i)$.

Similarly, we can write

$$\sum_{k=1}^{i} k^{1-\alpha} = \frac{i^{2-\alpha}}{2-\alpha} + \frac{i^{1-\alpha}}{2} + A_1(\alpha - 1) + \frac{(1-\alpha)\, i^{-\alpha}}{12}$$

Note that in this case the second-order term is $O(i^{1-\alpha})$.

Putting together these two terms we have $\sum_{k=1}^{i}(i-k)k^{-\alpha} = A_0(\alpha) i^{2-\alpha} + A_1(\alpha) i + O(1)$. where $A_0(\cdot)$ is defined as Lemma 4. Note that the terms of order $i^{1-\alpha}$ cancel out exactly. ☐

Proof of Lemma 5. The proof is similar to the proof of Lemma 4, and thus omitted. ☐
